Thus the Lenhartz method has won for itself a place in the treatment of gastric ulcer. It is true that the objections to that part of it which deals with the giving of nourishment immediately after hemorrhage may have to be reconsidered on account of the occasional untoward results that have been reported. But at least it has called attention to the undesirability of the prolonged under-feeding practiced especially by physicians who have carried Von Leube's principles to an extreme not countenanced by Von Leube himself, by undue prolongation of the period of rectal feeding. Lenhartz' diet must not be taken as an invariable one, but undoubtedly, as Lambert [65] and others have recognized, is to be varied to some extent according to local habits of diet and to individual peculiarities of patients, yet such variation can be readily affected without in the least changing the application of underlying principles. It is true that the Lenhartz treatment has not been proved to be actually better than the Von Leube treatment, and it may be that combinations of the two such as Senator's and Zweig's may be better than either, but at least we are now provided with a choice of treatments. When one treatment fails, as either treatment must do in some cases, the other may be instituted in its place instead of resorting to untried expedients.

Senator [63] aims to avoid the possible mechanical irritation of milk curds and at the same time to secure combination of free acid and adequate nutrition immediately after hemorrhage by the use of gelatine and of cream and butter. He begins treatment with a warm 10% solution of gelatine, sweetened and flavored with lemon, a tablespoonful every hour or oftener, and by giving in the first twenty-four hours 30 gm. of fresh butter

and ½ liter of cream, the butter in frozen pellets, and the cream beaten, with or without freezing. The blood still remaining in the alimentary tract is supposed to furnish sufficient protein, but a small amount of albumin is sometimes given in addition. Later the butter may be partly replaced by olive oil or almond milk. While this diet is small in bulk, its acid-binding power and its caloric value are relatively high.

Articles describing treatment of gastric ulcer have also been written by Rosenfeld,[76] who emphasizes the value of fats, especially cream, and increases or diminishes the relative proportion of albumin or carbohydrate according as hyperacidity or hypo-acidity is present; by Sternberg[77] with emphasis upon finely divided, mechanically non-irritating foods, the preparation of which he describes at length; by Linossier[78] and by Rochester,[79] who describe methods based upon the Von Leube method, and by Thomson.[80] Few writers upon medical treatment have attempted to distinguish between gastric and duodenal ulcer, and even those who have attempted the distinction have not modified their treatment when the ulcer is believed to be duodenal and not gastric.

A number of accessory measures in the treatment of gastric ulcer have been discussed, notable among which is the olive oil treatment, first advocated by Cohnheim in 1902. Difficulty has been encountered in prevailing patients to take the olive oil; on this account Senator,[82] Bloch[81] and others have substituted oil of sweet almonds or almond milk (a tablespoonful of powdered sweet almonds to a glass of hot water, emulsified, followed by peppermint, if necessary) or the following prescription of Bloch: ℞ Tinct. belladonnæ, ʒi; Olei amygdalæ dulcis, ʒi; Vitelli ovi uni, Aquæ ad ʒi. M. Ft. emulsio. Sig. One tablespoonful three times a day. Köhler[82] has given olive oil in gelatine capsules of 3 gm. each — six to ten a day. Rutimeyer[83] has reported striking results from the use of olive oil 100 ccm. every morning in 100 cases. Borbjaerg[84] has found the effect of this increased by the suspension in it of 10 gm. of bismuth.

The value of bismuth has long been recognized from its power of coating over the surface of an ulcer. But since nitrite poisoning has occurred in a few cases, attempts have been made to find a substitute. Meyerle[71] has used bismuth subcarbonate with satisfaction, also escalin, a preparation of finely divided aluminum devised by Klemperer, recommended also by Jacobson.[85] Hort[86] in England and Katzenstein[7] and Fuld[87] in Germany have treated cases by means of horse serum prepared to supply the theoretically deficient bodies which are supposed after Weinland[33] normally to combat gastrolysis and autodigestion of the stomach. The results of the former, however, are not conclusive, and those of Katzenstein and Fuld have not yet been formally reported; judgment upon this method must, therefore, be reserved.

To stimulate mucus secretion as a possible protection to the stomach, Kaufmann[39] has reported benefit from the use of silver nitrate, either ½ gr. doses internally or by lavage with 1:2,000 solution. Ewald[74] gives a dram of 1:1500 solution three times a day in certain cases. Surmont and Dubois[88] have shown that in animals bismuth has a marked effect in increasing mucus secretion.

To counteract hypersecretion Von Tabora[89] recommends the continued use of atropine, subcutaneously. Petri[90] has shown that solutions of hydrogen peroxide have a powerful effect in reducing acidity; he gives 1 to 3 ccm. internally in 200 to 300 ccm. of water in the morning or practices lavage with a ¼ to ½% solution.

Ewald[74] and Bourget[91] support the use of a gelatine solution containing ferric chloride, given either by mouth or by tube. Bourget also uses soft tablets prepared as follows: Gelatine, water and glycerine, āā 100 ccm., are dissolved with gentle heat; 50 ccm. liq. ferric chloride are added with stirring; the mixture is then allowed to cool and solidify in tablets of 1 ccm. each. Bourget's treatment consists of a diet of milk and zwieback or rice given at 8 A.M., 12 M. and 6 P.M.; two or three hours after each meal is given a ferric chloride gelatine tablet followed in half an hour by sodium bicarbonate solution.

The treatment of gastric hemorrhage is discussed by a number of authors. The hemorrhage in gastric ulcer, like other hemorrhage, tends to spontaneous cessation by reduction of blood pressure and by clotting of blood in the eroded vessel. In all but a small proportion of cases this process leads to a favorable outcome without treatment, but in certain cases where the bleeding is arterial and from a vessel of unusual size it is fatal in spite of all treatment; repeated or long-continued bleeding from smaller vessels may also lead to dangerous exsanguination. It is in these latter cases that treatment may make the difference between a favorable and an unfavorable result. The usual treatment of gastric or duodenal hemorrhage following Von Leube has been absolute bodily rest, an ice-bag to the epigastrium, morphia to quiet peristalsis and cessation of all mouth feeding. Hoover[6] has disputed the value of the ice-bag, Lenhartz has dispensed with morphia and Lenhartz and Senator have attempted immediate feeding as already described; yet rest, ice-bag, morphia and fasting are still made the basis of treatment by most clinicians. The use of old-fashioned styptics given by mouth has been abandoned except that of ferric chloride used with gelatine by Ewald,[74] or in solution for lavage in severe cases by Bourget.[91] Lavage with ice-water is advocated by Ewald,[74] but is regarded as unsafe by others. Weintrand[75] gives intravenously a 10% salt solution.

The use of adrenalin by mouth, 30 drops of 1:1,000 solution, has in recent years been advocated by Von Leube.[57] Müller[59] mentions cases where this has been of no avail, and Zweig[70] disputes its desirability on the ground that it may increase acidity, as it has been shown to do by Ynkawa.[92] Yet so many authors mention the adrenalin treatment with favor that it may be accepted as having won a place in the treatment of gastric hemorrhage.

SURGICAL TREATMENT FROM THE MEDICAL POINT OF VIEW.

With the recent prominence of gastric surgery it is important for the physician to have a clear understanding of its present status, particularly as to what assistance the surgeon can offer in the treatment of cases of gastric and duodenal ulcer, simple or complicated, and with what risk and with what hope of benefit.

Since gastro-enterostomy is by far the commonest operation, certain considerations as to its method of action which have been illuminated by recent work deserve mention. Gastro-enterostomy was at first devised to relieve pyloric stenosis. Next it was applied to uncomplicated gastric and duodenal ulcer with the idea of relieving the ulcer to some extent of the constant contact with gastric juice, but especially in the earlier cases with uncertain success, leading in some instances to obstinate vomiting of bile, cachexia and death. This led Cannon and Blake [93] to institute experiments in animals to determine the action of gastro-enterostomy in the presence of a patent pylorus, with the startling result that the stoma was found to refuse to serve as an outlet so long as the pylorus remained open. These results of Cannon and Blake have been confirmed by work of Legett and Maury, [94] of Guibe [96] and of Rovsing. [95] But the increasing success of gastro-enterosotomy in man as a method of treatment of ulcers without stenosis in itself establishes a presumption that the phenomonon in animals cannot be entirely parallel to what occurs in human cases of gastro-enterostomy. Furthermore, that the new opening from stomach to jejunum in human beings upon whom gastro-enterostomy has been performed may functionate whether or not the pylorus is obstructed is shown by the work of Pers, [96] who collected forty patients upon whom he had performed gastro-enterostomy from a few months to six years previously and traced the emptying of their stomachs by x-ray after a bismuth meal. In 38 of these 40, the stomachs discharged through the stoma rather than through the pylorus, and in the remaining two the route of discharge was uncertain. In all of these cases the stomach was emptied more rapidly than normal. Only 17 of them had at operation shown organic strictures of the pylorus. Jonas, [95] Schmieden [95] and Gray [97] have observed the stoma functionating in man. Gray [97] calls attention to an important anatomical consideration emphasized by Cunningham, but not sufficiently recognized by surgeons, that the stomach is not a one-compartment organ, but is divided by a band of muscle fibers, the *sphincter aditus vestibuli*, into two parts, the saccular cardiac portion and the tubular pyloric portion of greater peristaltic activity. To perform its function satisfactorily the stoma must be situated in the pyloric portion. While it is generally so placed by the surgeon, sufficient care is not exercised to insure this. Mayo's rule, for instance, that the stoma should lie vertically below the cardiac orifice, does not sufficiently guard against a stoma being placed in the cardiac portion where it can have little effect. In gastro-enterostomy performed with proper placing of the stoma close to the pylorus, Gray has seen by x-ray the bismuth meal pass out through the stoma in preference to the pylorus even though the pylorus was patent.

Aside from motor considerations, changes in the chemistry of digestion following gastro-enterostomy, notably a diminution of acidity found by some authors, have been supposed to play a part in the healing of gastric ulcers. To this question little has been added to what is mentioned by Goodall and Joslin [98] in 1907, except the work of Schönheim [99] confirming the usual presence of bile and pancreatic juice and of diminished acidity in the stomach contents of patients after gastro-enterostomy.

But whatever the cause of benefit after gastro-enterostomy in cases of gastric and duodenal ulcer, the statistics of surgical treatment leave no doubt that such benefit does occur. Statistics of different surgeons vary widely — between those of the Mayos,[2] who report, from 234 traced cases of gastric and duodenal ulcer, 80% cured, 9% improved, 4% not improved and the remainder dead, but only in 2 cases from causes connected with the stomach, and from 106 cases of duodenal ulcer, 82% cured, 9.5% improved, 5.7% not improved and a mortality of 2.8%, and those collected by Bettman and White [100] (150 cases) in which there was an operative mortality of 10%; 12% died in the first year and 14.6% died within five years after operations; 60% were cured or much improved and the remainder not improved. From a general survey of the literature [101] the impression obtained as to what can be expected from the present surgical treatment of gastric and duodenal ulcer may be roughly stated as follows: Approximately 60% of cures, improvement in half of the remaining cases and a mortality of 5%. As shown by the writings of Moynihan and of a number of other English surgeons, the treatment of duodenal ulcer by gastro-enterostomy has been considerably more successful than that of gastric ulcer; also gastric ulcers have been more successfully treated where they were situated at or near the pylorus. When it is remembered that the great majority of cases treated surgically are of a class which cannot be compared with those cases from which the medical statistics are compiled, but rather belong to the class of failures of medical treatment, even the less favorable of these surgical statistics show benefit from resort to surgery.

Operations other than simple gastro-enterostomy have been practiced by some surgeons, by ligation of vessels, or infolding and suturing of the base of the ulcer to guard against perforation and occlusion of the pylorus. These procedures appear not to increase the danger of the operation and may be of benefit.

Many surgeons, notably Rodman [53] and Payr,[102] counsel the resort to resection on the least suspicion that the ulcer may become malignant. The value of resection of suspicious cases is emphasized by the results of Kocher,[103] who reports 140

cases of resection for cancer with 30 permanent cures. But it must also be remembered that resection hitherto has greatly increased the mortality.* Thus the statement of Payr [102] that even a family history of cancer should warrant resection cannot be accepted without question.

The indications for surgical interference have been much discussed, physicians advising operation with reluctance and surgeons advising exploratory laparotomy at an early period. But as Mayo [2] has said, there need by no such dispute; that only cases that have failed to yield to a reasonable amount of medical treatment should be considered surgically. This is an excellent statement, correcting alike those physicians who have held that gastric and duodenal ulcer become surgical diseases only for their complications, and those surgeons who have advised premature operation.

The view expressed chiefly by English surgeons that duodenal ulcer should be treated surgically as soon as the diagnosis is made, since they believe that duodenal ulcers do not heal under medical treatment, must be questioned in the light of Codman's [3] findings. That healed duodenal ulcer is not found at autopsy may be due to the fact that duodenal ulcers heal without visible scar.

The surgical treatment of complications of gastric and duodenal ulcer is sufficiently well recognized and require but passing mention in a medical discussion. The treatment of recurrent hemorrhage has been advanced by increased knowledge of the situation of ulcers, and by the procedures of Rovsing [104] of illumination and instrumental inspection of the interior of the stomach at operation. That pyloric obstruction demands operation is no longer disputed.

The results obtained in gastric and duodenal perforation have been noteworthy. These perforations high in the gastro-intestinal tract cause peritonitis of a type which when promptly treated is frequently cured. The surgical results of perforation stated by Deaver,[105] of 50% recoveries in all cases and of 75% recoveries where operation was performed within twelve hours, emphasize the physician's responsibility for prompt diagnosis and surgical interference.

Reports of Societies.

AMERICAN SURGICAL ASSOCIATION.

MEETING AT WASHINGTON, D. C., MAY 3, 4, 5, 1910.

[Concluded from No. 16, p. 623.]

DISCUSSION.

DR. ARTHUR DEAN BEVAN, of Chicago: There is a point of technic I wish to emphasize after an experience with some 20 cases in which the Kraske operation was performed. That is, during the Kraske operation we do not employ a single ligature, but simply as we come to the tissues on the sides of the incision freeing the rectum, massive 10-inch or 12-inch clamps are put on the tissues, for instance, high up on the levator ani muscles and on the inferior hemorrhoidal vessels which supply the rectum and the lower part of the sigmoid. With the employment of these clamps there is less risk of hemorrhage and a greater saving of time than if an attempt is made at ligation.

DR. JOSEPH C. BLOODGOOD, of Baltimore: One of my first cases, operated on about six years ago, was such that we were able to save three inches of the anus and rectum, making a suture of the sigmoid which was brought down, and this patient has not only been as well as before, but has perfect function.

DR. ALEXANDER H. FERGUSON, of Chicago: In some of these cases I have resorted to the combined operation in two stages to advantage. Open the abdomen, take the proximal end of the bowel, make an artificial anus, invert the distal end into the rectum — that would be one operation; then, when the patient is in good condition, remove the rectum from below, the bowel being already inverted giving ready access to the mass. By the use of clamps without ligatures the operation can be done in a few minutes.

DR. JOSEPH A. BLAKE, of New York: I have had more experience with the combined operation than with any other; I have done twelve consecutive operations in that way without any mortality. The mortality is less if a permanent colostomy is done; it avoids infection and the operative field is kept comparatively clean, and it also affords the opportunity of removing the whole growth at the lower part of the bowel. This procedure should be confined to those cases at the middle of the rectum or above, and those in which the anal sphincter is involved and has to be removed.

DR. G. E. ARMSTRONG, of Montreal: In the low cases where the sphincter has been involved I have sometimes succeeded in getting a satisfactory sphincter by bringing the upper ends down through the lower fibers of the gluteus maximus. One such case operated upon ten years ago now has perfect control.

DR. WILLIAM J. MAYO, of Rochester, Minn. (in closing): We have some very satisfactory cases of union between the sigmoid and lower portion of the rectum, and the rule has been, when made from above it has been all right, but when made through the posterior incision, or through the vagina, there is ulcer and fistula. In regard to permanent colostomy, I have often regretted not employing this procedure, because some of our deaths have been due to infection.

I wish to emphasize the point that it is practically impossible to make honest percentages of cases such as these, for the reason that if all cases which cannot be traced are counted as dead, the mortality rate would mount up. This is the only way, however, to consider such cases of which we have no absolute record, and proves the inaccuracy of any percentages which we may try to strike.

CHORIOCARCINOMA. REPORT OF A CASE OCCURRING IN A PATIENT WITH AN INFANTILE UTERUS.

A. PRIMROSE, M.D., C.M., M.R.C.S. Eng., Toronto, Canada: Tumors variously described in individual instances as chorio-epithelioma, deciduoma malignum, syncticma maligna, etc., have hitherto been considered as overgrowths of chorionic villi which invade the blood sinuses of the uterine wall, and then, rapidly disseminating, present the clinical picture of great malignancy.

A neoplastic growth of this character may occur after normal pregnancy. In addition, however, it may follow miscarriage or it may make its appearance after the removal of a vesicular mole. In cases of ectopic gestation the tumor elements have been demonstrated in the gestation sac. In 1903, Teacher published the results of an exhaustive study of chorio-epitheliomata, and his views have generally been accepted that they arise in connection with pregnancy and originate from the chorionic epithelium which is of fetal epiblastic origin.

The tumor removed presented the characteristic elements of a choriocarcinoma with a very large proportion of Langhan's cells showing metaplasia and mitosis. A few isolated masses of the syncytium were also present.

These tumors may exhibit an histological structure in which fully formed villi may be present or the cellular elements of that structure in varying proportion. Secondary growths are common in the vagina or in the lungs, but occasionally metastases occur in the liver, kidney and other organs. There is a relationship between pathological processes resulting in a neoplasm and physiological activity because the invasion of the maternal uterine tissues by the villi occurs as a normal process in pregnancy. Increased activity in this direction may lead to malignant infiltration and tumor formation. A further fact of interest is that in normal pregnancy normal chorionic elements are carried to the lungs and lodged in the pulmonary capillaries and there undergo absorption.

The clinical course of chorioma presents great variation. The primary growth may disappear spontaneously and this may occur whilst secondary metastases continue and produce a fatal issue. Hemorrhage, pain, anemia and extreme emaciation are frequent symptoms, and where metastases occur in the lungs, then we have cough and hemoptysis.

Ewing's classification is the most valuable guide for prognosis and treatment.

Chorio-adenoma in which the structure of the villus with its normal histological arrangement is reproduced.

Choriocarcinoma in which Langhan's cells are chiefly in evidence and where marked mitosis is observed.

Syncytial endometritis where the maternal tissues are invaded with wandering cells derived from the syncytium.

Syncytioma where transitional types are in evidence.

Of these, the choriocarcinoma is extremely malignant and is probably invariably fatal. The other forms present great variation in their degree of malignancy and may even disappear spontaneously or after partial removal.

Where spontaneous disappearance does occur, Teacher has shown that the process is brought about by fibrosis and encapsulation.

PROGNOSIS AND OPERATIVE TREATMENT OF FRACTURE OF THE BASE OF THE SKULL.

JOSEPH RANSOHOFF, M.D., of Cincinnati, Ohio: The paper was based on an analysis of 190 cases occurring during the last ten years in the Cincinnati Hospital. One hundred and twenty-four of the cases were fatal. The prognosis is influenced by the depth of the coma chiefly, and even in greater degree by the fixed condition of the pupils. Of 42 patients with non-reacting pupils, 41 died. In five years there were 19 operations, trephining or decompressive, with 7 recoveries. The conclusions of the paper were as follows:

I. There will always be a large mortality connected with basal fractures; death resulting from primary shock, brain laceration or hemorrhage. Thirty-seven per cent of the fatal cases die within six hours or less, and 56% die within twelve hours. It is not probable that the mortality of this class of cases can ever be reduced with or without operation. They are primarily fatal.

II. Twenty-three per cent of the fatal cases die during the second twelve hours of the first day; and 6% die during the second day. They are the cases in which the coma is not profound; in which the pupils are not fixed; in which the breathing is not stertorous and in which there is not complete muscular relaxation. With a slow, full pulse and lumbar puncture indicating hemorrhage and increase of intracranial pressure, a trephining operation is indicated. In the doubtful cases an operation is indicated.

III. In this class of cases, where facilities for the major operation of trephining are not at hand, repeated lumbar puncture should be essayed. This procedure

may be destined to take the place of decompressive operations.

IV. There is a large group of cases in which there is complete consciousness or in which there is a somnolence or milder degree of coma, and in whom the concomitant symptoms do not indicate a grave intracranial trauma either to the brain or its vessels. The pupils though uneven react; involvement of one or more cranial nerves may be evident. The symptoms singly or collectively are not ominous at any time. Eighty per cent of this class of cases have a tendency to get well with or without operation. They should not be operated on unless the symptoms indicate an increase of intracranial pressure from hemorrhage, beginning cerebral edema or distinct localizing (cortical) symptoms.

V. There is a distinct class of cases in which operation is indicated. They are cases which seemingly not severe in the beginning grow progressively or suddenly worse, showing signs of increased intracranial pressure. Decompressive operations may save a considerable proportion of them.

VI. It has yet to be determined where the trephining should be done to obtain the best results. Since most fractures involve the anterior or the middle fossa, subtemporal trephining is doubtless the procedure oftenest indicated. When, however, an hematoma in the mastoid or occipital region indicates an involvement of the posterior fossa, the operation should be subtentorial. To relieve the subtentorial tension by an opening made in the temporal region is illogical and may be dangerous. I attempted it recently in a cerebellar tumor, the site of which could not be determined. The patient succumbed within two weeks with symptoms of bulbar paralysis.

DISCUSSION.

Dr. Frank E. Bunts, of Cleveland: In an ordinary case of fracture of the base of the skull in which the blood pressure can be obtained, a beginning choked disk and edema and hemorrhage in the brain detected, the decompression operation should be performed, and in many such cases we may expect altogether beneficial results.

Dr. Joseph C. Bloodgood, of Baltimore: Up to the present time I have been unable to find any case of epilepsy following an injury to the skull in which some piece of the skull was removed, either by operation or by the injury itself. This would rather substantiate the view that epilepsy is more apt to be started up by changes in pressure than by actual injury.

Dr. G. E. Armstrong, of Montreal: If in these cases the pressure is subtentorial, as indicated by the respiration, aspiration of the cerebrospinal canal may prove very injurious.

Regarding Dr. Bloodgood's remarks, I would like to report two instances where epilepsy has followed in the presence of considerable defect in the skull; one following the kick of a horse in a young man, where there was rupture of membrane, loss of brain tissue with considerable defect in the skull remaining, and epilepsy beginning a couple of years later; the other, in a man injured in the frontal region, in which there is a considerable defect in the skull, and epilepsy has followed.

A METHOD OF OVERCOMING THE SHORTENING IN OLD FRACTURES TREATED BY THE OPEN METHOD.

Edward Martin, M.D., of Philadelphia, Pa.: It was because of the complete futility of any method of traction which could be applied to the leg and feet in the case of an ununited fracture of the femur with 2½ inches of shortening that the present method of overcoming the shortening was devised. It consists in a long strong canvas strip pocketed in the middle and looped at the ends. The bones at the seat of fracture are freed, the pocket is slipped over the proximal end of the distal fragment, the ends of the canvas strip are carried in the long axis of the limb, and in the loops is fixed a cord to which are attached the weights. By thumb pressure the bone is kept from angling out of the wound, and weights up to 100 lb., or even more, are attached to the rope. In from three to five minutes the shortening is overcome. Only those structures which interfere with proper placement are stretched, and this is done so thoroughly that there is but slight tendency to the reproduction of deformity.

DISCUSSION.

Dr. Richard H. Harte, of Philadelphia: In regard to extension, I consider a pulley similar to that used on boats, a double and single pulley, to be the best type to use. These should not be close together, but enough line between them to allow of manipulation of the limb by the operator. After a thorough incision has been made and the ends of the bone exposed, you can disengage the bands of tissue by the employment of steel elevators. It is important to do as little damage as possible to the tissues. I do not consider silver plates strong enough to hold the bones in position and, therefore, would always advise the use of a heavy steel plate such as that suggested by Lane.

Dr. Albert J. Ochsner, of Chicago: I would like to describe a method which we use almost entirely. It consists in the slow stretching of the muscles instead of the rapid stretching, and the only thing that is peculiar about the method is the application of rubber adhesive strips to as high a point above the seat of fracture as is possible. For instance, instead of applying the rubber adhesive up to the fracture, it should be applied over the entire length of the thigh; then, with no more than 24 lb. of weight, we have, in every fracture where there has not been a union, been able to stretch the muscles sufficiently to replace the fractures without making a resection of the ends. In cases where there is a union in malposition, the muscles will stretch to a marked extent. It is important to use two Lane plates, with two screws at each end in order to keep the bones from slipping.

Dr. James E. Thompson, of Galveston: I think the important point is that it is not the contraction of the muscles which prevents reduction, it is hemorrhage, and after this blood clot has been evacuated, the bones can be held in proper position.

Dr. Harry M. Sherman, of San Francisco: The method of extension described by Dr. Harte I do not consider as good as where two hanks of yarn are applied as perineal straps, the weight coming on the tuberosity of the ischium. On the foot is put another hank of yarn. The pulling upon the bones has been measured, and over 200 lb. of weight have been applied in some cases without injury to the ligaments of the ankle or knee, and that is sufficient to pull out any tissue interfering with the approximation of the bones.

Dr. Edward Martin, of Philadelphia (in closing): The length of the screws used in adjusting these plates should be the thickness of the bone, should be threaded up to their heads, and to hold the plate in place it is required that they penetrate entirely through the bone and no more.

In cases of extension, we prefer to use the old-fashioned resin plaster, properly made, because the rubber plaster always excoriates the skin.

FRACTURE DISLOCATIONS OF THE OS INNOMINATUM.

Harry M. Sherman, M.D., of San Francisco, Cal.: The paper made the point that simple uncomplicated fractures of the pelvic bones was not of necessity a

serious lesion, but that healing could be expected in an ordinary way, as after a fracture of a bone of an extremity; that the really serious lesion was the complication of injuries to the bladder, the intestines or the vascular system; that injuries to the bladder were more likely to occur when the fracture had been due to antero-posterior compressive force; that injuries to the urethra were more apt to occur when the fracture was due to transverse compressive force; that the present indications were to open at once the space of Retzius and make a reverse catheterization and perineal section with lateral incisions in the groin and perineum for drainage of all areolar planes. With this technic the mortality should be reduced to about 33% as against 60%.

DISCUSSION.

DR. ARPAD G. GERSTER, of New York: I have in my experience a case of fracture of the female pelvis on the left side in which there was no injury of the urethra, although it was compressed to such an extent by a solid blood clot that retention followed and had to be relieved for fifteen or sixteen days by the use of the catheter. The woman recovered, there was no other injury present. Another case was one in which there was fatal hemorrhage following fracture of the pelvis. Post-mortem revealed extensive laceration of one of the common iliac arteries and subperitoneal hemorrhage.

ON MOMBURG'S METHOD OF ARTIFICIAL ANEMIA BY SUPRAPELVIC CONSTRICTION.

ARPAD G. GERSTER, M.D., of New York, N. Y.: In reporting a successful case of his own, the author presents the history and present status of the method of obtaining artificial anemia of the pelvis, its organs and of the lower extremities by the elastic constriction of the abdominal aorta. The procedure has been employed hitherto in Germany in more than 300 cases by a large number of surgeons, gynecologists and obstetricians, whose reports are in the main very favorable.

The method consists in the application of the Esmarch principle to the waist and to the abdominal aorta, which thus, by the superposition of from two to six turns of the elastic cord, is compressed against the lumbar spine. The apprehension that the necessary amount of constriction might damage the gut has not been justified by experience. The interruption of the aortic blood current is regularly followed by a marked rise of the blood pressure, and its restoration by a still more marked cardiac depression, which, in patients afflicted with arteriosclerosis, myocarditis or even well-compensated valvulous lesions, may attain alarming proportions. Hence, Momburg's method is not suitable in these cases. In healthy and young individuals, however, its use is free from danger.

By this procedure the surgery of injuries, tumors and of acute or chronic suppurative disorders of the pelvic skeleton and contents has been rendered infinitely more safe than ever before.

Gynecology also has readily appropriated the new procedure. Mackenroot has shown that the most radical forms of attacking carcinomata of the uterus have become safe and bloodless by its aid. Isolation of the ureters and the removal of the retroperitoneal lymphatics along with the diseased womb are thus done with the bloodless precision of a post-mortem dissection.

The method's greatest utility for life-saving, however, has been demonstrated in post-partum hemorrhage, where Momburg's constriction affords the advantage of an easy and prompt control of the loss of blood, a measure which on account of its simplicity is available to every practitioner, to the midwife and even to intelligent laymen. An additional advantage of the measure is that not only is the bleeding arrested by it, but an energetic and lasting contraction of the flaccid womb follows the artificial anemia.

DISCUSSION.

DR. JOSEPH RANSOHOFF, of Cincinnati: I have seen this method pursued in one case, and in this no ill effects resulted from its employment.

DR. HARRY M. SHERMAN, of San Francisco: I would suggest that where this method is used there is the same vasomotor paralysis below the point of constriction as after the employment of the ordinary Esmarch bandage on the extremities, and that this may be a reason for returning the vessels to the circulation gradually, otherwise there might be hemorrhage into the arteries.

DR. RUDOLPH MATAS, of New Orleans: I have pursued some experiments among some students with this method, but found that a fair test of it could not be made unless the patient was anesthetized in order to gain complete relaxation. From our very imperfect experiments, however, it was shown that in all weak hearts you are liable to have prompt failure; instead of noting the usual increase in blood pressure, there will be a fall, and this we feel indicates an inability on the part of the heart to keep up. I would not advise the use of the Momburg constrictor in any patients suspected of having any cardiac irregularity, but believe it will prove of great benefit in producing artificial anemia in strong, robust individuals without being followed by any ill effects.

DR. ARPAD G. GERSTER, of New York (in closing): I would especially emphasize the point that this constrictor is not indicated in cases in which there is any disturbance with the cardiac function. It has proven particularly valuable in post-partum hemorrhage in healthy individuals.

Book Review.

Symptomatic and Regional Therapeutics. By GEORGE HOWARD HOXIE, A.M., M.D. With 58 illustrations in the text. New York and London: D. Appleton & Co. 1910.

As is stated in the preface, this volume contains "the material collected for the course in general therapeutics recommended by the Committee on Curriculum of the American Medical Association — a recommendation adopted also by the Curriculum Committee of the Association of American Medical Colleges." After an exposition of the principles and methods of general treatment of pain, fever, itching, insomnia, constipation, vomiting, hiccough, cough, asthma, shock, emaciation, obesity, convulsions and localized inflammations, there is presented a systematic consideration of the treatment of the principal diseases regionally grouped. The volume concludes with miscellaneous notes on remedies and a brief *materia medica* based on the United States Pharmacopeia, giving the properties, dosage and uses of one hundred and twenty-five common drugs. The book, which contains a great deal of valuable information, is well written, arranged and illustrated, and should be an exceedingly useful work of therapeutic reference for general practitioners.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, OCTOBER 27, 1910

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

MEDICAL ASPECTS OF LATE MARRIAGE.

IT has become the fashion nowadays to decry late marriages as involving not only disappointment to individuals, but detriment to the race. This attitude proceeds partly no doubt from the natural assumption that the sooner one enters the blessed state of matrimony, the happier he must be, and partly from certain so-called anti-race-suicide propaganda which have led us to believe that the earlier a family begins to raise its children, the more and the better will be the progeny. No doubt in some cases this is true. *A priori* it would seem that children born during the years of their parents' most exuberant physical vigor should have a better chance in the struggle for existence than those begotten after the years of decline have begun. Nevertheless, it is not certain that this is necessarily the fact. Certain forms of life, particularly some plants, put forth their greatest reproductive energies late in life. Moreover, even if it were true that the children of young parents have an advantage over others, it must be remembered that fitness for survival does not consist solely in physical efficiency, but in such a combination of physical, mental and moral qualities as shall best enable the individual to escape the dangers and adapt himself to the conditions of his environment.

Now in our day, and especially among the classes in which late marriages prevail, those conditions are highly complex and require, almost more than physical efficiency of the animal type, the higher qualifications which only civilization can produce. Such qualities may conceivably be more fully transmitted, because more fully attained, by parents beyond the first flush of youth. From this point of view late marriage becomes an actual process of natural selection, an inevitable stage in evolution.

One of the weightiest arguments against late marriage is that it protracts the period of celibate temptation, during which men are liable to commit indiscretions that may have the gravest effect for evil on succeeding generations. Those who survive this period unscathed, however, are thereby the better fitted for survival and the more likely to transmit to posterity the powers of inhibition which have raised man above the brutes.

It is unfortunately true that late marriages often mean small families, but this is not necessarily so, and if they mean also the development of a fitter type, the price is well paid and no greater than the sacrifices man has been compelled to make at every step of his ascent. In children born of older parents, too, there is sometimes observed a delay of maturity, which protracts for them the early years of educational acquisition and lessens the hardship of late marriage. People are accustomed in this world to value most the things they have to wait for, and the experience of our race has shown that everything which tends to raise ideals of marriage is for the ultimate good of the race, though it may seem to sacrifice the individual. Really it does not sacrifice the individual, except in outward and inconsiderable ways.

Unquestionably in our country the age at marriage is steadily rising, especially among the more educated classes. From a medical as well as a sociologic point of view, however, it does not seem that this need be regarded with alarm as an unmixed evil spelling ruin to the race. It is rather a natural evolutionary phenomenon, as much a part of our progress as our first step in the erect posture. No doubt there is a point beyond which late marriage becomes absolutely destructive and undesirable, but on this side of that point there is still a sufficient margin to permit the advantages which accrue from later marriage without sacrificing the higher happiness of the individual or the ultimate good of the race.

CULTIVATION OF ANIMAL CELLS OUTSIDE THE BODY.

ATTENTION is called to the important experimental work, recently reported by Carrel and Burrows in the *Journal of the American Medical Association*, on the "cultivation of adult tissues and organs outside the body." The results of this research are not merely of scientific interest,

but may offer possibilities of great practical value. If the cells of various human and animal tissues and organs can be successfully grown on culture media, after the fashion of micro-organisms, and transplanted into successive cultures, there will be available opportunities never before open for the study of cellular biology, for observing the physiology and habits of animal cells and investigating the very nature of the life process. Not only normal but pathologic cells may be so studied, and in particular those anarchistic cell-growths known as neoplasms. Moreover, it is conceivable that such cells, cultivated outside the body, might be available under certain conditions for retransplantation into the body of the original or of another host.

Much yet remains to be learned in all these subjects, but the observations of Carrel and Burrows seem, according to their promise at least, of great potential value, and a worthy contribution to contemporary medicine from the Institute of which the profession has such high hopes for the future.

CERTIFIED MILK.

In a bulletin issued on Oct. 15, the Milk Commission of the Suffolk District Medical Society announces its certification of the following dairies: "The Warelands," Highland Lake, Mass.; Massachusetts Agricultural College, Amherst, Mass.; Cherry Hill Farm, Beverly, Mass.; Middlebrook Farm, Dover, N. H.; and Miles River Farm, Hamilton, Mass.

The problem of securing and maintaining reliable sources of pure milk supply will always be one of the greatest importance to any community. At a hearing before the State Cattle Bureau in Lowell, Mass., on Oct. 21, questions of milk inspection were discussed from the standpoint of the consumer, of the producer and of the physician. There is undoubtedly considerable dislike on the part of farmers to inspection by the State Board of Agriculture. Whether such inspection would be more satisfactory to all if placed in the hands of the State Board of Health is a proposition that has been suggested and has found many advocates. Such a system has been opposed on the ground that it gives undue authority to the medical profession, whose standards may perhaps be unreasonably high, but on the other hand it would give consumers a greater sense of security, would insure uniformity of inspection methods and would generalize the advantages of certified milk now enjoyed only in certain localities.

HEALTH OF THE UNITED STATES ARMY.

The recently published annual report of the Surgeon-General at Washington indicates continued improvement in the health of troops in the United States army service. The total number of deaths in the army during the past fiscal year was 370, of which 228 were from disease and 142 from trauma. The admission rate for sickness, representing the number excused from duty for any ailment, was approximately 86.6%. This seems extraordinarily high, and is indeed higher than in other countries, but is lower than it has been in the United States in former years. The non-effective rate, which is the real measure of disability from injury and disease, was during the past year only 41.48 per thousand, as contrasted with 42.68, 46.17 and 49.79 for the three preceding years. It is interesting to note, in comparison, the statement recently published in England, that the non-effective rate of the British army in India has been reduced 50% in the past ten years.

The Surgeon-General's report contains the further important information that of 11,338 persons in the army who have thus far received antityphoid inoculation, only 3 have since had typhoid fever, and none of these has died. On the basis of these convincing figures it is recommended that this protective inoculation be made a routine compulsory procedure throughout the army.

FURTHER CONDEMNATION OF OYSTER BEDS.

In the issue of the Journal for Oct. 6 we noted the recent condemnation, by the Rhode Island Board of Shellfish Commissioners, of "275 acres of oyster beds at Bristol, in that state, as unfit for use on account of pollution by sewage from the city." This action was in consequence of the question raised some time ago by Dr. Wiley, of the United States Public Health and Marine-Hospital Service, whether the growing of oysters in waters used for drainage does not violate the provisions of the pure food law. As a result the local commissioners have made a complete investigation of the waters of Narragansett Bay, which have been divided on the basis of bacterial cultures into three classes: good, doubtful and bad; and all beds of those of the latter class have been condemned. In addition to those condemned at Bristol, beds at Providence have also been condemned to the value of $30,000, and at Warren, beds valued at $50,000. This action should result in improving the quality of oysters on the

market, and in making them safer for consumption as food. Nevertheless, even though protected by antityphoid inoculation, the cautious and discreet will probably for some time still "beware the mollusca," and refrain from the raw oyster as a dietetic luxury, unless they know where he was raised.

CONTINUANCE OF THE BOSTON HOSPITAL SCHOOL.

In the issue of the Journal for Oct. 13 we commented editorially on the proposed discontinuance of the Boston Hospital School at Franklin Park. Protests against the closing of this school were made by many physicians and by the Boston Association for the Relief and Control of Tuberculosis. Last week a conference was held between the mayor, the Board of Trustees of the Boston Consumptives' Hospital, the Boston School Board and the Boston Board of Health, as a result of which it was announced that the Hospital School will be continued for the present. It was also recommended at this meeting that in every school building hereafter erected by the city there be provided an open-air room for tuberculous and pre-tuberculous children.

In commenting on this recommendation an editorial in one of our daily papers pertinently remarks that fresh air should not be limited to such rooms, but should be more liberally admitted to all schoolrooms. This suggestion might well be extended to many public and private buildings. The prophylaxis of tuberculosis is even better than the continuance of hospital schools for its cure.

DENTISTS IN THE ARMY AND NAVY.

At the annual meeting of the Northeastern Dental Association, held in Boston last week, there was considerable discussion over the failure of the national government to afford proper recognition to dentists in the army and navy of the United States. At present, instead of ranking with officers of the line, they are classed with masons, mechanics and other contractors. For some years a committee of the National Dental Association has been endeavoring to secure at Washington the legislation necessary to modify these conditions and establish a satisfactory status for dentists.

Other subjects under discussion were the provision of free dental clinics and public dispensaries in large cities, and the teaching of dental and oral hygiene in the public schools. At the closing session, Dr. Henry A. Kelley, of Portland, Me., was elected president for the ensuing year; Dr. Frederic T. Murless, Jr., of Hartford, Conn., and Dr. Andrew J. Sawyer, of Manchester, N. H., vice-presidents; Dr. David Manson, of Burlington, Vt., treasurer; and Dr. Edgar O. Kinsman, of Cambridge, Mass., secretary.

MEDICAL NOTES.

Annual Meeting of the American Medical Association. — The annual meeting in 1911 will be held at Los Angeles, June 27 to 30 inclusive.

Hospital Burned at Winnipeg. — On the night of Oct. 18 a building at Winnipeg, which was in temporary use as a scarlet-fever hospital, was destroyed by fire. Forty-four children, patients in the building, were all safely removed.

Some Death-Rates in 1909. — Mortality statistics for the year 1909 show that of American cities with a population of 100,000 or over, New Orleans, La., that year had the highest death-rate, 20.2 per 1,000. Fall River, Mass., stood second, with a rate of 19.1, and Washington, D. C., third, with a rate of 19.

Free Distribution of Tuberculin. — As an evidence of the extent to which cattle in this country are tested for tuberculosis by their owners, it is stated that during the past year 400,000 ampoules of tuberculin were distributed free by the Federal Bureau of Animal Industry to cattlemen for use in making this test.

Death of Prince Francis of Teck. — News from London reports the death on Oct. 22 of Prince Francis of Teck, brother to the present Queen Mary of England. Presumably his Royal Highness died of empyema, as he is said to have recently undergone two surgical operations after a long illness with pleurisy.

Nobel Medical Prize. — The Nobel medical prize has been awarded to Prof. Albrecht Kossel, of Heidelberg. Professor Kossel is in his fifty-eighth year. He is a native of Rostock and he studied medicine there and in Strassburg. He devoted himself from his graduation in 1881 to physiological chemistry. He has done much pioneer work in the artificial production of organic material.

American Association of Railway Surgeons. — The seventh annual convention of the

American Association of Railway Surgeons, which was held last week at Chicago, was attended by about 400 members. Among the subjects discussed were the abolition of the common drinking cup, the ventilation of cars and the abatement of smoke and dust. A special committee of five was appointed to co-operate with state and municipal boards of health to secure better sanitary conditions in railroad cars and stations and along railroad rights of way.

The Cholera Situation. — There seems to have been little change in the cholera situation in Italy during the past week. From Oct. 17 to Oct. 23, 111 new cases of the disease were reported in that country, with 55 deaths. These figures, which show a slight increase over those of the previous week, probably under-represent the true incidence and mortality of the infection. Report from Brazil states that the steamer *Araguaya*, from Southampton and Lisbon, is now under quarantine at the port of Rio Janiero, owing to the occurrence of several deaths from cholera on board during the voyage. No further cases or suspected cases have been discovered on ships reaching the United States during the past week. Of the three actual cases of cholera detained at the Swinburne Island Hospital, one has died and two are now convalescent.

Alvarenga Prize of the College of Physicians of Philadelphia. — The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Senor Alvarenga, and amounting to about one hundred and eighty dollars, will be made on July 14, 1911, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered.

Essays intended for competition may be upon any subject in medicine, but cannot have been published. They must be typewritten and must be received by the secretary of the college on or before May 1, 1911.

The Alvarenga Prize for 1910 has been awarded to Dr. M. Katzenstein, of Berlin, Germany, for his essay entitled "The Formation of an Arterial Collateral Circulation in the Kidney."

Increased Supply of Radium. — In an editorial in the issue of the Journal for Oct. 20, we announced the special meeting of the Surgical Section of the Suffolk District Medical Society next Monday, Oct. 31, to be addressed by Dr. Wickham on the clinical use of radium. In a recent number we have also noted the enormous cost of radium. It is interesting in this connection to learn by report from London that a considerably increased yield of radium is now being obtained from the pitchblende mines of Cornwall. Pitchblende is an ore of uranium, from which radium is extracted by a special process devised by Sir William Ramsey. During the past month 55 cgm. of pure radium have been produced at the Trenwith mines near St. Ives, and it is expected to increase the output to a gram a month. This not only assures a continuous supply of radium, but will probably lead to some decrease in its cost.

Suit for Late Arrival in an Obstetric Case. — An interesting suit for $5,000 damages has recently been filed before the Supreme Court of the District of Columbia by a patient against her physician for failure to reach her in time to render the obstetric services for which he had been engaged. The plaintiff alleges that the physician absented himself from his office without leaving word where he could be found, as a result of which he did not receive her summons till three hours after it was sent, and in consequence reached her house after the baby was born. The plaintiff further avers that, owing to the physician's absence at this time, she sustained personal injury resulting in subsequent disability, on the ground of which the claim for damages is made.

The moral obligation of a physician to hold himself in readiness for an expected obstetric call is, of course, generally recognized. Whatever the merits of the present case, it will be important to learn to what extent he may be held legally responsible for failure to answer such a call with sufficient promptness, if the fault for that delay can be proved to be his own.

Electricity for Cataract and Seasickness. — One is sometimes led to wonder if there be any ailment of the flesh, from warts to apoplexy, which electricity has not been alleged to cure. It is unfortunate that an agent of known therapeutic value should be so woefully abused and paraded as an advertising snare. But the mysterious is always attractive, and many would rather be healed by the occult than by the rational. The two latest suggestions for the medical use of electricity are in the treatment of cataract and of seasickness.

Of course these are hardly to be taken seriously. It is not so surprising that electricity should seem to cure seasickness, in which the treatment

is largely suggestion. That it should offer prospect of benefit in cataract seems so remote a possibility as to be hardly worth consideration as long as surgery offers such excellent relief. It is to be feared that it will hardly remove the opacity of the patient's eye better than that of the mind's eye in him who employs it.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston.— For the week ending at noon, Oct. 25, 1910, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 50, scarlatina 19, typhoid fever 35, measles 17, smallpox 0, tuberculosis 68.

The death-rate of the reported deaths for the week ending Oct. 25, 1910, was 14.35.

Boston Mortality Statistics.—The total number of deaths reported to the Board of Health for the week ending Saturday, noon, Oct. 15, 1910, was 205, against 181 the corresponding week of last year, showing an increase of 24 deaths, and making the death-rate for the week, 15.94. Of this number 109 were males and 96 were females; 200 were white and 5 colored; 138 were born in the United States, 64 in foreign countries and 3 unknown; 51 were of American parentage, 126 of foreign parentage and 28 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 33 cases and 3 deaths; scarlatina, 9 cases and 0 deaths; typhoid fever, 30 cases and 2 deaths; measles, 4 cases and 0 deaths; tuberculosis, 42 cases and 22 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 25, whooping cough 2, heart disease 31, bronchitis 3. There were 16 deaths from violent causes. The number of children who died under one year was 50; the number under five years, 64. The number of persons who died over sixty years of age was 46. The deaths in public institutions were 83. Anterior poliomyelitis, 1 case and 1 death.

Of the above infectious diseases the following were non-residents: Consumption, 3 cases and 5 deaths. Scarlet fever, 1 case. Typhoid fever, 1 case.

Deducting deaths of non-residents, the total is 174 and the death-rate is then 13.53.

Massachusetts Medical Benevolent Society. — The annual meeting of the Massachusetts Medical Benevolent Society is to be held this afternoon, Oct. 27, at the Boston Medical Library.

Diphtheria at Worcester. — On Oct. 21 five cases of diphtheria in a single school were reported to the Board of Health at Worcester, Mass. Suitable precautions have been taken to prevent the spread of this minor outbreak.

Bequests to Medical Charities. — The will of the late Mary A. Puffer, of Lynn, Mass., filed for probate at Salem, Mass., last week, contains the following bequests to medical charitable institutions: To the Lynn Hospital, $5,000; to the Union Hospital of Lynn, $1,000 and one third of the residuary estate; to the New England Peabody Home for Crippled Children, Boston, $1,000; and to the Boston Floating Hospital, $1,000.

Violations of Milk Laws in Malden. — In the district court at Malden, Mass., a local dealer was last week fined $50 on each of two counts, the first for having in his possession for sale milk to which 12% of water had been added, the second for having in possession milk containing formaldehyde. Another dealer before the same court was fined $25 for offering for sale cream below the required standard. The occurrence of such violations shows the need of continued vigilance on the part of milk inspectors.

Hospital Concerts for November. — It is announced that during the month of November the concerts of the Hospital Music Fund will be given as follows: On Nov. 2, at the Soldiers' Home, Chelsea; on Nov. 6, at the Free Hospital for Women, Brookline; on Nov. 13, at the Somerville Hospital; on Nov. 20, at the House of the Good Samaritan, Brookline; on Nov. 24 (Thanksgiving Day), at the Massachusetts General Hospital; and on Nov. 27, at the Vincent Memorial Hospital, Roxbury.

NEW YORK.

Diphtheria at Hamilton College. — An outbreak of diphtheria, stated to be rather mild in character, has occurred at Hamilton College, in Clinton, and as a result the forty students and one of the faculty with quarters in Emerson Hall have been placed under quarantine. Up to Oct. 7 twelve cases had been reported.

A Death from Cholera at Sea. — The steamship *Taormina*, from Naples and Genoa, which arrived at quarantine on Oct. 22, reported that on the 18th a woman steerage passenger had died at sea from cholera, after three days' illness, and by way of precaution Health Officer Doty had all the steerage passengers of the vessel transferred to Hoffman Island for observation.

ENDOWMENT OF ROCKEFELLER INSTITUTE. — On the day that the new hospital of the Rockefeller Institute was opened it was announced that Mr. Rockefeller had added to the endowment of the institute $3,820,000 in securities having a par value of that amount. This makes the total income-bearing endowment $6,420,000, and the total amount of Mr. Rockefeller's gifts to the institute, including land and buildings and earlier gifts for medical research, $8,240,000. A formal statement issued on this occasion by the trustees is in part as follows: "The latest addition to the resources of the institute has also been made the occasion for an important development in the organization of the institution as a public trust. To-day for the first time the Board of Trustees contemplated by the charter has come into being, and has legally taken possession of all the property of the institute, thus establishing it perpetually as an independent foundation. The Board of Trustees is initially constituted as follows: John D. Rockefeller, Jr., Frederick T. Gates, William H. Welch, Starr J. Murphy and Simon Flexner. The function of this board is to hold and care for the property of the institute, including the investment of its endowment funds, and to hold the entire income at the disposal and under the full control of the Board of Scientific Directors, which is constituted as follows: Dr. William H. Welch, of Baltimore, president; Dr. T. Mitchell Prudden, of New York; Dr. L. Emmett Holt, of New York, secretary and treasurer; Dr. Christian A. Herter, of New York; Dr. Simon Flexner, of New York, director of laboratories; Dr. Hermann M. Biggs, of New York, and Dr. Theobald Smith, of Boston. The final establishment of the Rockefeller Institute, with its present generous endowment, is the culmination of a series of carefully considered gifts, each one based on a thorough demonstration of existing needs and on evidence of competent stewardship of funds previously intrusted. . . . The hospital, which will profit largely by the new income, is not to be regarded as a separate institution; it is merely a part of the working equipment for medical research controlled by the one board of directors. Being now intrusted with by far the largest sum of money available for medical research, and with a wonderfully generous and perfect equipment at their command, the directors have a high sense of their responsibility to the public for the careful discharge of their great trust." Some realization of the care bestowed upon construction and the perfection of detail in the hospital may be obtained from the fact that it is estimated that, according to the expense of erection and equipment, each of the seventy beds which form its complement cost the large amount of $16,000.

7. ABBE, T. *A Fracture of the Pubic Bone.*

5. Wolbarst gives some of his observations on the effect of Ehrlich's "606," and reports seven cases of his own. He concludes that, if not a complete specific, it is certainly the most potent remedy for syphilis yet produced. The primary lesion shows distinct evidences of healing within a few days. Secondary lesions disappear within two weeks. In many cases gummata that have resisted mercury and the iodides for years have disappeared in from three to six weeks and have not since recurred. [L. 5. Cabot, in an analysis of 1,000 autopsies and clinical findings, studies mistakes in diagnoses. In brief, he

found correct diagnoses made in aortic stenosis, in 61% of the cases; in aortic regurgitation, in 84%; in chronic myocarditis, in 22%; in arteriosclerosis, in 60%; in thoracic aneurysm, in 50%; in cardiac hypertrophy and dilatation, in 66%; acute and ulcerative endocarditis, 39%; acute pericarditis, 20%; lobar pneumonia, 74%; bronchopneumonia, 33%; phthisis, 59%; miliary tuberculosis, 52%; acute nephritis, 16%; chronic glomerular nephritis, 74%; chronic interstitial nephritis, 50%; cerebral hemorrhage, 67%; cerebral tumor, 72½%; septic meningitis, 64%; tuberculous meningitis, 72%; gastric cancer, 72%; peptic ulcer, 36%; hepatic cirrhosis, 61%; typhoid fever, 92%; diabetes mellitus, 95%. He draws the following conclusions from his analyses: (1) Never make a diagnosis of uremia in a patient seen for the first time in an acute illness characterized by coma or convulsions. Such diagnoses rarely turn out right. (2) Never make a diagnosis of ptomaine poisoning without definite chemical evidence. General peritonitis or a tabetic crisis is usually the correct diagnosis. (3) In patients whose symptoms begin after forty-five years the actual diagnosis is more likely to be arteriosclerosis, hyperthyroidism, dementia paralytica or pernicious anemia rather than hysteria, neurasthenia or psychoneurosis. (4) Diagnoses of tertian malaria in patients whose symptoms resist quinine more than three days are almost invariably wrong. (5) Bronchial asthma beginning after forty usually spells heart or kidney disease. (6) Epilepsy beginning after forty usually means dementia paralytica or cerebral arteriosclerosis. (7) Typical migraine is often a symptom of unrecognised brain tumor or chronic nephritis. (8) Most cases of "bronchitis" mean tuberculosis, bronchopneumonia or multiple bronchiectatic cavities. (9) Aside from the immediate results of acute infections (such as scarlet fever, diphtheria, tonsillitis and pneumonia), "acute" nephritis usually turns out to be chronic. (10) Acute gastritis and gastralgia usually mean appendicitis, gallstones or peptic ulcer. (11) Pus in or near the liver is often mistaken for serous or purulent pleurisy, for it produces identical signs in the right chest, posteriorly. (12) An x-ray of the shinbones may give the first hint of an active syphilitic process in the joints or internal viscera.

14. Hirshberg advances the novel theory that the reactions such as urticaria, hyperemias, albuminuria, glandular swellings, resulting from the ingestion of certain foods, such as crabs, lobsters, berries, mushrooms, oatmeal and tomatoes, are anaphylactic phenomena, the system becoming sensitized to these various substances.

1. *Smith, T. *The Reaction Curve of the Human and the Bovine Type of the Tubercle Bacillus in Glycerine Bouillon.*
2. *Park, W. H., and Krumwiede, C., Jr. *The Relative Importance of the Human and Bovine Types of Tubercle Bacilli in the Different Forms of Human Tuberculosis.*
3. De Witt, L. M. *Some Observations on Phenol as a Clearing Agent in Histologic Work.*
4. Torrey, J. C. *The Viscosimeter as an Aid in the Detection of Liquefying Bacteria.*

1. Theobald Smith reports in this article further study of the "reaction curve" derived from the culture of tubercle bacilli. The "curve" is the record of the reaction change in the medium in which the bacilli are grown. The author uses bouillon with 5% glycerine added; enough of this is placed in flasks of uniform size to make a layer 1.5 cm. deep; the flasks are then plugged with cotton-wool and the mouths covered with tin-foil. From time to time 5 ccm. of the bouillon are withdrawn and titrated. From the experiments which he has made, he has found that with bacilli of the human type there is a decrease of acidity for the first ten to fifteen days, after which there is a rapid increase, which reaches a maximum in from thirty to forty days. Cultures of the bovine type, on the other hand, show a decrease in acidity which in twenty to thirty days reaches alkalinity. The reaction then remains alkaline for at least thirty days more, and then slowly becomes acid.

Several other observers agree with these results. Griffith's results, which differed, were shown to have been secured by growing the bacilli in a thicker layer of bouillon which did not contain enough glycerine to insure an excess of what the bacteria could use, thus materially altering the conditions of the test.

The curve, Smith believes, is a valuable means for differentiating the two species of bacilli.

2. Park and Krumwiede present an exhaustive study of the question, how much of the tuberculosis in human beings shows evidence of bovine origin. Investigating 436 cases, they found that in the great majority of these the bacilli isolated could be grouped, according to their virulence and peculiarities of growth, in one of two quite distinct classes, i. e., as of the human or as of the bovine type. Their differences the authors believe to have been acquired by long-continued growth in cattle or in men; it is not possible, they think, for one type to acquire the characteristics of the other with any rapidity.

The writers give at length analytical tables of their own cases and of those reported by others. The final summing up is as follows: Of 1,042 cases, there were in adults sixteen years and over, 677 human, 9 bovine; in children five to sixteen years, 99 human, 33 bovine; in children under five years, 161 human, 59 bovine. From these figures it appears that the possibility of infection from milk, milk-products and meat, especially in children, is a matter of large importance.

11. Higgins, H. *Certain Urinary Reactions and Their Significance in Chronic Conditions of Faulty Metabolism.*
12. Yearsley, M. *A Retrospect of Otology.*

1. Morris, discussing the surgical treatment of renal calculus, considers the following points: (1) When bilateral renal calculus should be operated upon simultaneously; (2) when nephrectomy should be the treatment for ureteral calculus; and (3) when the surgical treatment of renal calculus should not be checked or modified because of the presence of tubercle bacilli in the urine.

4. Bolton considers the following questions: (*a*) How does an acute gastric ulcer heal? (*b*) Do any conditions exist which can delay the healing of such an ulcer? (*c*) Why does a chronic ulcer not heal? He has studied these questions by means of artificially produced ulcers in cats. By injecting a gastro-toxin (prepared from goat serum by rendering the goats immune to injected gastric cells of a cat) into the stomach wall of cats he was able to produce at will typical gastric ulcers. He has studied the healing on a normal diet, the effects of position, of the hyperacidity of the gastric juice, and the effect of diminished acidity;

the effects of acute ulcer upon the production of hydrochloric acid and the effects of bacterial finding. He goes into the production of motor insufficiency and the effects of pyloric stenosis upon the healing of acute gastric ulcer. All these points studied in the cat he applies to ulcer in human beings, citing several cases.

5. In discussing the early recognition of cancer of the womb, the writer concludes as follows: (1) Attend to all symptoms suspicious of cancer and instruct the patients upon the importance of them. (2) Examine all cases of bleeding or abnormal discharge. (3) Operate as soon as the diagnosis is established, if the disease is not too far advanced. [J. B. H.]

12. MEYER, L. *The Cause of the Wassermann Reaction. (Remarks on a Paper in No. 35 of this Journal on This Subject.)*

1. Richter takes up the question of renal dropsy, mentioning many of the different theories and the experimental proof which supports or refutes them. Our present knowledge shows that there must be present three factors. These are an injury to the kidney which causes retention of salt and water, a hydremia dependent upon this, and, finally, an injury to the vessel wall with increase of permeability. He considers that the salt retention is the cause of the water retention, but not of the edema which is dependent on the vessel injury. The practical point of treatment, however, rests upon the salt retention and its hydremia because this is the only factor that can be influenced by treatment. At present we have no method of curing the renal or circulatory injuries. [C. F., JR.]

12. BACHEM, C. *New Remedies, Patent Medicines and Specialties.*
13. COENEN, H. *The New Attempts in the Treatment of Fractures.*

9. Kromayer states that it is as easy to treat patients with "Preparation 606" as with mercury, and that he has not found confinement in bed necessary. He uses small doses and administers the drug once or twice a day and allows his patients to walk about as they will during the course of the treatment.

11. Heymann reports two cases of postpartum hemorrhage successfully checked by means of the Momberg constriction. Not only does this have the effect of mechanically checking the hemorrhage by pressure on the blood supply of the pelvic organs, but also, by the anemia produced in the uterus, that organ contracts most firmly and forcibly, expelling the placenta and making manual extraction unnecessary. He quotes authorities who have had good results with this method, and one who reports failure. [J. L. H.]

4. AGULHON, H. *Influence of the Reaction of the Media upon the Formation of Melanine by Diastatic Oxidation.*

1. Richet has continued his experiments with crepitine and has further facts to report than in his recent publication in this journal. As a result of his experimental work he concludes that with the injection of an antigen both toxogenic substance and an antitoxic substance are formed. This former substance, when united with some more of the antigen, forms a substance which he calls "apotoxin" and which is very poisonous and causes symptoms ranging from excitability and pruritus to coma and death from respiratory paralysis.

He presents a number of observations which in themselves individually point to the correctness of this view, but which taken collectively make it almost absolutely certain.

His theory is that anaphylaxis is a method of the body to keep a foreign albumen from getting a hold on the individual cells. In this way the specificity of the organisms are maintained. Chemical poisons do not seem to act in the same manner as these albuminoid ones.

AUGUST, 1910.

1. *QUÉNU, E. *Icterus in Hydatid Cysts of the Liver.*
2. BOECKEL, A. *Traumatic Dislocations of the Tarsal Scaphoid, Particularly Double Dislocations.* (Continuation.)
3. KÜSS, G. *Pelvic Pericolic Strictures, Principally in the Female.* (Conclusion).
4. MONOD, C., AND VANVERTS, J. *Documents and Remarks on the Treatment of Arterial Aneurysms.* (Conclusion.)

1. From a study of 50 personal cases of hepatic echinococcosis, and comparison of these with others reported in the literature, Quénu concludes that icterus is much commoner in the course of hydatid disease than is generally supposed; that such icterus may be due to compression of the biliary passages at the hilus or to angiocholitis; that the former, however, is an exceptional, and the latter the habitual, cause. In a few cases he considers that the angiocholitis is the terminal episode of a septicemia occasioned by an infected hydatid cyst; more often that it is the result of the irruption into a primary duct of the contents of a broken cyst. Such rupture may be spontaneous, or may be due to minor trifling accidental violence. Clinically, the jaundice due to angiocholitis is variable; that due to compression is progressive.

5. PICQUÉ, R. *Subphrenic Abscesses.* (Conclusion.)

3. The authors present a further study on the ever-fertile subject of the causes of congenital dislocation of the hip. They conclude that any anomalous position of the lower extremity may cause dislocation of the hip after the first half of fetal life. Certain pelvic malformations may produce the same result. The immediate cause of such dislocations is often dystrophy of the peri-articular muscles. In newborn children, especially in girls, the hip can often be easily dislocated. The writers believe that so-called anthropologic congenital dislocation of the hip occurs in reality after birth.

5. MANTELLI, C. *Contribution to the Study of Oblique Internal or Vesico-Pubic Inguinal Hernia.* (To be continued.)

1 and 2. The question of anaphylaxis in malignant disease is one of considerable importance, on which little work has as yet been done. The authors of these two papers consider it from different points of view. From two series of experiments on guinea pigs Maragliano concludes that it is impossible to obtain in them a specific active anaphylaxis of carcinoma. From four series of similar experiments Isaja concludes that the fall of temperature following the injection of cancerous human serum into guinea pigs is not a specific anaphylactic phenomenon, and that, therefore, passive anaphylaxis in guinea pigs cannot be used as an aid in the diagnosis of malignant tumors.

4. Brugnatelli's article emphasizes the importance of histologic examination of metastases in the diagnosis of a primary tumor.

4. GAMBAGLIO, R. *Fractures of the Carpal Scaphoid.* (To be continued.)

3. Abetti made a study of the leucocytic granulations in pus from 24 cases of suppurative disease of various origin to determine whether there were any relations between the causative agent of the infection and the nature of the leucocytes. His conclusions are as follows:

(1) That in the majority of bacterial suppurations, the principal constituent elements of the pus are polymorphonuclear neutrophiles.

(2) That in gonorrheal suppurations there is a slight proportional increase of polymorphonuclear eosinophiles

(3) That in chemical subcutaneous suppurations there is an exudation of polymorphonuclear neutrophiles with desquamation of the lymphatic endothelium.

(4) That the iodophilic reaction is always positive, whatever the nature of the suppuration.

These results are the same as those reached by Leoncini in his study of the cytology of peritoneal exudates.

[R. M. G.]

Correspondence.

PARIS LETTER.

SOLAR CURE OF SURGICAL TUBERCULOSIS.

[*From Our Special Correspondent.*]

PARIS, Sept. 27, 1910.

Mr. Editor: A friend of mine, just back from Switzerland, tells a remarkable tale about an experiment he has there seen in the matter of treatment of surgical tubercular lesions of all varieties, osseous, nodular and serous. Experiment, however, is hardly the proper term, as the treatment has now been in use for seven years; the establishment my friend visited consists of three sanatoria, capable of accommodating upwards of three hundred patients, and is directed by a certain Dr. Rollier, with an assistant at each sanatorium. It will perhaps be best to relate the entire history of this place.

Dr. Rollier is a young surgeon who for four years was assistant to Kocher at Berne. In 1903 his wife showed signs of pulmonary trouble, and he took her off to Leysin for the altitude cure. Leysin is a place that deserves a few words of description.

Most travelers are familiar with the eastern end of Lake Geneva, the Dent du Midi, and the Valais, leading to the Simplon. On the northern side of this valley, above Aigle and almost opposite the Dent du Midi, at an altitude of 1,200 to 1,500 meters, lies a beautiful alp, as the Swiss call it, a high pasture-ground, sloping gently up to the pines and rocks, and facing due south. On this slope there has always been a peasant's agglomeration of chalets, but a few years ago, when the sanatorium movement became so popular, the natural advantages of the spot were discerned and one sanatorium after another was erected along the upper edge of this alp. These were, however, solely for pulmonary tuberculosis, and the results obtained from them have been very satisfactory, owing to certain peculiarities inherent in Leysin's position: unusual absence of wind, intense solar radiation, and great purity of air.

The village of Leysin and the Dent du Midi.

It was to this resort that Dr. Rollier accompanied his patient, and as he himself had no other resources but his practice, and as there was no vacancy for him on the staff of the sanatoria, he established himself in the village as local general practitioner. About this time he heard reports of what Dr. Bernhardt, of Samaden in the Engadine, was doing in the way of treating sluggish wounds of all sorts by solar radiation, and went over there to look into the method; he then returend to Leysin, began little by little to apply the system to surgical tuberculosis, and has now evolved a treatment of which he is perfectly master and which bids fair to place him in the foremost rank of the men who have been of use in the fight against tuberculosis. His system is as yet hardly known, as his communications on the subject have scarcely spread beyond local societies; but my informant is a first-class Paris surgeon, who went carefully over the ground for his own instruction, so that I fancy there is no mistake about the matter. It is guaranteed, furthermore, by Dr. Rollier's personal surgical qualifications, and again by the evident practical success of the venture from a business point of view.

He takes no medical cases, though naturally he gets a few in patients with external lesions as well, but he says that the method appears to work admirably in pulmonary trouble, as was also demonstrated by the entire recovery of his wife. His ordinary patients are cases of fungous arthritis, Pott's disease, tubercular cystitis, peritonitis, glands of all sorts, tubercular skin lesions, etc., as well in adults as in children, though of course the majority of his patients are children. He does not neglect the usual means of treatment, — injections, plaster jackets, x-rays, etc., — but combines them with his method, which consists in acting on the system in general, not on the local lesion, by solar radiation.

Leysin, les Frênes, altitude 1,360 meters. Dr. Rollier's clinic.

His sanatoria face the sun, as was to be expected, and are abundantly provided with balconies and open roofs on to which the beds are wheeled from the rooms and dormitories. The patient's entire body, front and back, is

Sun-cure in winter. A gallery of the chalet.

exposed to the sun, with or without apparatus, and winter as well as summer, during a time that varies according to the child's condition of health and state of training. He begins with exposure of the feet only for five minutes *ter die*, first one side, then the other. The patient must be apyretic or almost so, — under 38°. The period of exposure is then gradually lengthened until it reaches as

much as six and seven hours *per diem*. So great has become Dr. Rollier's skill and so delicate his "touch" that he breaks his patients in without so much as an acute sunburn, until finally they become an almost walnut-brown hue. And he has found that the quicker and more intense this pigmentation, the better the patient's outlook; it takes place most rapidly with dark subjects, less so with blonds, and least so with the venetian-red type, which corresponds with our ordinary basis of prognosis in this complaint.

At first sight the idea of a little child being exposed *naked* to several hours of sunlight on a balcony in Switzerland in midwinter at an altitude of 1,500 meters, with everything about it covered with several feet of snow, is simply terrifying. What mother could be brought to accept such apparent risks as these! This difficulty has to be turned by getting the parents used to the treatment by degrees, in the same manner as is done with the patients. They are shown the initial five-minute exposure, which is not very dreadful, and the rest is a question of time. Besides, ideas are contagious; the parents meet other patients in the hotels, and are told of the anguish the latter passed through, but how pleased they now are with the results, so that the trouble on this score is not very great. But for the uninitiated to see a picture of a lot of naked, brown children, some with plaster jackets on, playing on beds in the brilliant sunshine in midwinter with the country about them buried in snow, is, to say the least, startling. Some cases, Pott's disease of the spine, for instance, are made to lie still in the sun on their beds; these children wear white hats, and flying screens are put up to keep the glare out of their faces.

The galleries in winter.

The treatment at Leysin is based partly on altitude and partly on solar radiation, and the explanation of the tolerance of even little children in a state of nudity to solar exposure in winter at that altitude lies, of course, in the fact that the circumambiant air is not at all what a person would be inclined to think. It is in reality very hot on those balconies, the temperature reaching 45 and 50° C. even in December, January and February (113–122° F.). So it is not surprising that the children not only stand it, but like it. This is furthermore helped out by the almost total absence of wind, for it is doubtful whether such a treatment could be carried out in a place exposed to cold winds, no matter how much sun there were.

Not among the least of the attractions of Leysin is the view from the sanatoria, though probably this is a matter of minor interest to the children than the toys on their beds. In the foreground is the snow-covered alp, and the low, flat chalets, also buried in snow; then some dark, pine-grown hills, and back of them still the magnificent Dent du Midi with the group of snow mountains of which it is the most prominent portion.

One of the first results of the solar radiation treatment is the disappearance of pain, — in coxálgia, for instance, where this symptom decreases or is relieved sometimes by a single exposure. As regards tubercular glands, Dr. Rollier says that this is certainly the best treatment known; they are either absorbed spontaneously and vanish, or else soften under the influence of the light and disappear after one or two evacuating punctures without leaving any mark.

The solar radiation has not only an extraordinary invigorating action on the system in general, but is a most powerful bactericidal agent as well, particularly in winter, when the power of the heat rays is far distanced by that of the light rays. There is then no dust at all at Leysin, on account of the blanket of snow that is spread over everything, and there is nothing whatever in the atmosphere (very little moisture, even) to absorb rays; the sky is of an indigo blue, and the excursus between the maximum and minimum temperature of the twenty-four hours can be as much as 120° F.

Here is what Dr. Rollier has to say about mountain climates in general: "A high mountain or alpine climate is the most favorable one for solar treatment. Solar radiation only reaches the lowlands after having passed through the atmospheric layer. The lower levels of this atmosphere, and in particular those of cities, are thick with dust, micro-organisms, aqueous vapors and humanity which absorb light in proportions that may extend to 90%; these layers of air laden with dust, which a physicist has called atmospheric sediment, are powerful absorbers of luminous and caloric radiations whose intensity is in direct relation to altitude. Furthermore, in the lowlands these opaque layers of air absorb the heat rays and protect the ground against their action; the air is hot there as well as the soil. In the mountains the case is altogether different. The transparent and dust-free air allows the solar radiation to pass freely through it so that none of its energy is held back. It can, therefore, act altogether on the soil and transmit its heat, while the air remains quite cool. This contrast between the power of the direct rays of the sun and the coolness of the atmosphere is one of the characteristics of mountain climates and is most favorable to the sun treatment, since the heat, modified by the cool air, is never unpleasant to patients as is the case in the lowlands, and the duration of the sun baths can be prolonged without any risk."

Patients are now coming to Dr. Rollier from all over Europe, but in particular from Switzerland, Germany, Austria and Russia.

My informant describes the results obtained by this method as "absolutely admirable." Its essential action resides in transforming the patient's general condition by this total exposure of the surface of the body to the action of the sun's rays. In treating spinal or hip trouble of tubercular origin the surgeon generally aims at ankylosis in a good position as the best he can do for the patient, and is quite content if he gets that, but with Dr. Rollier's system a *restitutio ad integrum* is frequently obtained, with free movements in the joints affected. Not only can this result be accomplished in the favorable cases of closed lesions at an early stage, but in some cases of open lesions, even in adults! Cases that formerly were considered practically hopeless, such as Pott's disease of the spine, with abscess by congestion open and infected, recover under the sun treatment, though such results are naturally not as brilliant as when the case can be treated earlier in the disorder. One patient that came under Dr. Rollier's care had twenty-five different tubercular lesions disseminated about the body and recovered! Another adult patient at the sanatorium gained 38 lb. in weight in six months on the sun baths alone.

The treatment is not a rapid one, nor was that to have been expected: all chronic disorders imply a chronic treatment. An ordinary case requires upwards of two years in the mountains. But even this is better than the classical surgical treatment by immobilization, and as has been remarked above, the ultimate outcome is far superior, with a free joint. It is preferable to send patients to Leysin in December and May, the beginning of the fine seasons, when they are going there for the first time; the winter treatment is superior to the summer, there is less wind, and all dust is smothered under the snow.

Dr. Rollier's success is all the more creditable to him in that it was achieved in spite of the united opposition of his medical confrères up at the pulmonary sanatoria; and one of the best proofs of the credibility of the reports that have come about his treatment is that the well-known surgeon, Roux, of Lausanne, is sending his cases up to Leysin.

"S."

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, OCT. 15, 1910.

LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND OTHER OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED OCT. 12, 1910.

WICKES, H. W., surgeon. Directed to proceed to New Orleans (Quarantine), La., upon special temporary duty. Oct. 10, 1910.

LUMSDEN, L. L., passed assistant surgeon. Directed to proceed to Huntsville, Ala., upon special temporary duty. Oct. 7, 1910.

MCCLINTIC, T. B. passed assistant surgeon. Granted fourteen days' leave of absence from Oct. 5, 1910.

MCLAUGHLIN, A. J., passed assistant surgeon. Directed to proceed to Chicago, Ill., upon special temporary duty. Oct. 10, 1910.

FRANCIS, EDWARD, passed assistant surgeon. Granted thirty days' leave of absence from Oct. 3, 1910.

RUCKER, W. G., passed assistant surgeon. Directed to proceed to Baltimore, Md., upon special temporary duty. Oct. 7, 1910.

SPRATT, R. D., passed assistant surgeon. Granted four days' leave of absence from Sept. 28, 1910, on account of sickness.

ALFORD, NEIL, acting assistant surgeon. Granted thirty days' extension of leave of absence from Aug. 29, 1910, on account of sickness, and fourteen days' annual leave from Sept. 28, 1910.

BARCLAY, JAMES, acting assistant surgeon. Granted thirteen days' leave of absence from Oct. 10, 1910.

BINGHAM, E. O., acting assistant surgeon. Granted fifteen days' leave of absence from Oct. 15, 1910.

GOLDTHWAITE, HENRY, acting assistant surgeon. Granted seven days' leave of absence from Oct. 6, 1910.

SCOTT, E. B., pharmacist. Granted twenty-three days' leave of absence from Oct. 17, 1910.

BOARD CONVENED.

Board of medical officers convened to meet at Stapleton, N. Y., Oct. 18, 1910, for the purpose of making a physical examination of a cadet of the United States Revenue Cutter Service. Detail for the board: Surgeon H. W. Austin, chairman; passed assistant surgeon W. A. Korn, recorder. Oct. 11, 1910.

SOCIETY NOTICES.

ASSOCIATION OF RAILWAY SURGEONS. — The twentieth annual meeting of the New York and New England Association of Railway Surgeons will be held at Hotel Astor, Broadway and 44th Street, New York City, Thursday and Friday, Nov. 3 and 4, 1910.

THE HARVEY SOCIETY. — The second lecture of the Harvey Society will be delivered by Prof. W. E. Castle, of Harvard University, on Saturday, Nov. 5, at 8.30 P.M., in the Academy of Medicine, 17 West 43d St., New York. Subject: Unit Characters in Heredity.

BOSTON MEDICAL LIBRARY IN CONJUNCTION WITH THE SUFFOLK DISTRICT MEDICAL SOCIETY. — Medical section meeting, John Ware Hall, Wednesday, Nov. 16, 1910, at 8.15 P.M. "Acute Poliomyelitis," John Lovett Morse, M.D. Discussion by Drs. R. W. Lovett, W. E. Paul and W. P. Lucas.

EDWIN A. LOCKE, M.D., *Secretary*, 311 Beacon St. HENRY JACKSON, M.D., *Chairman*, 380 Marlborough St.

SUFFOLK DISTRICT MEDICAL SOCIETY. — Stated meeting, Saturday, Oct. 29, at 8.15 P.M. "What Medical Societies can do for the Health of the People." Paper: By Mr. John Ritchie, Jr. (For two years member of the Boston Board of Health.) Discussion: Formal discussion by invited guests will be omitted; instead, it is hoped that there will be free general discussion by the members of the Society. Business: Election of Nominating Committee; Revision of the By-Laws of Suffolk District Medical Society. Refreshments after the meeting.

GEO. H. MONKS, *President*. DAVID D. SCANNELL, M.D., *Secretary*.

RECENT DEATHS.

DR. WILLIAM W. BALDWIN, who died of apoplexy last week at Great Bend, Pa., spent the greater part of his professional life in Italy, where he practised medicine at Rome and at Florence. He is survived by his widow, four sons and two daughters.

DR. GEORGE WHIPPLE PORTER, who died at Dorchester on Oct. 15, was born in 1847. He received the degree of A.B. from Brown University in 1870 and that of M.D. from the Harvard Medical School in 1874. He practised medicine in Providence, R. I.

DR. ABRAM BROTHERS, of New York, died on Oct. 15. He was graduated from the College of Physicians and Surgeons, New York, and afterwards served as interne at Bellevue Hospital. At the time of his death he was adjunct professor of diseases of women in the New York Post-Graduate Medical School and visiting gynecologist to the Post-Graduate and Beth Israel hospitals.

JAMES H. DENNY, M.D., formerly of Boston, and at one time a visiting physician at the Boston City Hospital, died at Vienna, Austria, Oct. 16, at the age of seventy-one years. He was a member of The Massachusetts Medical Society from 1863 to 1892.

BOOKS AND PAMPHLETS RECEIVED.

Treasury Department, Hygienic Laboratory, Bulletin No. 63. Digest of Comments on the Pharmacopeia of the United States of America and the National Formulary for the year ending Dec. 31, 1907. By Murray Galt Motter and Martin I. Wilbert.

Treasury Department, Hygienic Laboratory, Bulletin No. 67. The Solubilities of the Pharmacopeial Organic Acids and their Salts. By Atherton Seidell.

THE ETIOLOGY OF CHOLECYSTIC GALL-STONES.

BY W. IRVING CLARK, M.D., WORCESTER, MASS.

THE pathogenesis of gallstones has been a subject of great interest and continual investigation since the days of Galen. The large percentage of stones found at autopsy (7–10%) and the severity of the symptoms and complications have lead to an exhaustive study of the subject. While the definite cause of gallstones has not yet been established, so much progress has been made that it is now possible at least to draw a hypothetical picture of the different steps of gallstone formation derived from the hypotheses and results of various investigators. Such a picture should be of interest to the physician and surgeon in view of the wide range of complications which follow this condition.

In this paper a résumé of the theories of gallstone pathogenesis will be given, with a subsequent hypothetical picture of typical gallstone formation.

The hypotheses of pathogenesis of gallstones have considered almost every conceivable factor. Upon examination, however, these hypotheses fall into three broad groups which may be roughly classed as metabolic, histological and chemical.

Since gallstones consist principally of cholesterin and bilirubin calcium, the probable source of an over supply of these substances and the question of the method of their precipitation has formed the basis of each hypothesis.

In order to obtain a clear view of the field these hypotheses will be stated in brief and then considered in detail.

I. *Metabolic hypothesis.* — This hypothesis conceives increased biliary cholesterin and bilirubin calcium to be the result of some change in metabolism, which causes an increase of these substances in the blood. The liver then excretes them from the blood; they appear in the bile in abnormal amounts.

II. *Chemical hypothesis.* — This hypothesis conceives a precipitation of the cholesterin and bile pigment from the bile by some chemical change in the bile itself, due either to autolysis or to bacterial action.

III. *Histological or mucous membrane hypothesis.* — This hypothesis conceives the cholesterin and calcium of the bile to be formed entirely by the mucous membrane of the gall bladder and bile ducts, a catarrhal inflammation increasing the production of cholesterin and calcium.

The metabolic hypothesis was much favored up to the time of Naunyn. Austin Flint, Du Jardin-Beaumetz, Frerichs and others held this view, but following the work of Naunyn and his pupils the theory was not given as much support.

This was due to the fact that Naunyn fed dogs large quantities of cholesterin, and also injected it hypodermically, but was unable to recover an increased percentage of cholesterin from their bile.

These experiments, though apparently convincing at the time, are not above criticism. Thus, Herter[1] says that "it is impossible to insure prompt absorption from the intestine or from the peritoneum, and intravenous injections of finely divided substance (cholesterin is extremely insoluble) cause death from embolism." He furthermore concludes that "we cannot exclude the possibility that there are occasional disorders of nutrition attended with an increase of cholesterin in the blood serum and hence with an increase in the bile." As possible etiological factors he considers diabetes, arteriosclerosis and nephritis, basing his conclusion upon the finding of high cholesterin percentages or the presence of gallstones upon autopsy in these diseases.

Beer[2] has recently supported the metabolic hypotheses in an investigation of intrahepatic stones. He collected autopsy statistics upon twelve cases in which there had been obstruction of the common bile duct for a period of four to five weeks, accompanied by inflammation of the extra- and intra-hepatic ducts. These cases showed the classical conditions necessary for the production of gallstones, according to Naunyn. In seven of these cases the common duct was obstructed by stones; in five cases, by tumors. In the first series (the stone cases) he found many stones in the liver ducts, but in the second series of five cases, no stones were present. From this he argues that since the pathological conditions of the bile ducts were identical in both series, and one series, which already had gallstones lower down the tract, developed stones in the liver ducts, while the other series showed no stone formation; therefore, something more than mere stagnation of bile and infection of bile passages is necessary in the formation of stones. He suggests a derangement in the metabolic function of the liver as a probable etiological factor.

Howell,[3] in 1908, says, "It is assumed that cholesterin . . . is eliminated by the liver cells from the blood, which collects it from the various tissues of the body," while Hemmeter,[4] 1909, believes that gallstone formation may be due to pathologic metabolism of the liver.

Thus, though most authors hold strongly to some modification of Naunyn's mucous membrane hypothesis, they are not prepared to ignore the possibility of general metabolism as a factor in cholesterin and calcium production in the bile.

Chemical hypothesis. — Established by Thudicum[5] in days before the rôle of bacteria in disease was known, this hypothesis has had many supporters up to Naunyn. Following Naunyn's work the theory was allowed to drop until revived by Halia,[6] Gérard,[7] Kramer[8] and Bacmeister,[9] in the last four years.

Thudicum's hypothesis held that cholesterin and bile pigment were precipitated from stagnant bile as the result of an acidity which appeared in the bile after long standing. He believed that the acidity was due to the mucus in the bile and that this acidity caused a decomposition of the bile salts and alkaline carbonates which initiated a precipitation of cholesterin and bilirubin calcium. The possibility of such a reaction has

been acknowledged by all investigators, and since the discovery of bacterial action, attempts have been made to show that this acidity could be produced by such action upon the bile.

Thus Halia [6] inoculated sterile and filtered ox bile, rendered alkaline, with typhoid and colon bacilli, with a resulting change of reaction of the media to acid. Dunham,[10] however, repeating this experiment upon human bile, found that even a considerable growth of these bacilli produced a hardly perceptible change of reaction toward acidity in from seven to ten days. Criticism has been made that Dunham's experiments were not carried on over a long enough period.

Gérard [7] added colon bacilli to sterile bile. He then incubated and after some weeks obtained a precipitation of cholesterin. This precipitation he believed was due to a dissolution of the bile salts (through acidity of the bile).

Kramer [8] has recently (1907) performed an interesting series of test-tube experiments in which sterile tubes of mixed bile and bouillon were inoculated with B. typhosus and B. coli communis. After six months there was a semi-solid precipitate taking the form of the bottom of the tube and consisting of all the constituents of gallstones. Kramer concluded that gallstone formation was the direct result of the growth of micro-organisms in the bile. Just what the exact chemical nature of the decomposition is he is unable to say, but suggests that it is due to acid production by the bacteria. This would agree with Halia's findings. Baldwin,[11] examining the gall bladders of a number of cases having cholecystitis following acute infectious diseases, found the bile to be acid or neutral.

Following Kramer's work, Bacmeister [9] began publishing a series of revolutionary papers. He found that B. pyocyaneus and B. proteus likewise cause a precipitation of cholesterin in the bile. Not satisfied with this, he carried out experiments still further and found that cholesterin would separate out of sterile bile on long standing. He describes the successive steps of crystal formation which he was able to watch under the microscope. The first phase of the cholesterin is in the form of myelin droplets, at first very minute, but gradually increasing in size and forming amorphous clumps of cholesterin. Fine crystals, needle-like in form, as well as the typical flat platelets of cholesterin, separate from the droplets or the amorphous masses.

He viewed this process in sterile and infected bile, but noted that it occurred much more rapidly if epithelial cells were present. From these experiments he believes that cholesterin precipitation is due to autolysis of the bile which is markedly hastened by the presence of bacteria or epithelial cells.

Summing up in his monograph with Aschoff,[12] he says: "We find the radiate cholesterin stone, as a rule, in non-infected simply stagnant gall bladders.

"The morphology of radial cholesterin stone shows a slow crystallization out of the bile. The chemical building up of the stone arises from synthesis of normal, not decomposition of infected, bile.

"The constituents of the stone can be precipitated from normal bile without infection through simple decomposition (test tube experiments). The radiate cholesterin stone occurs almost solely as a single stone."

Mucous membrane hypothesis. — This hypothesis is also an old one. It was suggested by Budd as far back as 1845, and revived in 1887 by Bristowe, but it received its strongest support in 1892, when Naunyn [13] published his classical monograph on cholesterin.

According to Naunyn, the steps in the pathogenesis of gallstones are as follows:

I. Stagnation of bile in the gall bladder.

II. Introduction of non-virulent bacteria into the gall bladder, these bacteria setting up a catarrhal inflammation of the mucous membrane.

III. An extrusion of cholesterin in amorphous or myelogenous form from the diseased mucous membrane.

IV. Collection of amorphous cholesterin about small masses of detritus and bacteria with subsequent crystallization.

V. Increasing precipitation of cholesterin from the inflamed mucous membrane.

VI. Precipitation of bilirubin calcium from the bile around the cholesterin nucleus.

VII. Replacement of the calcium in whole or in part by cholesterin through infiltration.

This theory has been slightly modified by subsequent experiments. Thus Wakeman [14] injected strong solutions of bichloride of mercury, carbolic acid and other irritating sterile drugs into the gall bladders of dogs. After starving the dogs for three days, they were killed and the bile analyzed. In all the dogs thus treated, the cholesterin content of the bile was much increased and there was proliferation and desquamation of the epithelial cells. He, therefore, concludes that bacteria *per se* are not necessary to cause cholesterin precipitation, as a catarrh of sterile origin produces a like result.

Adami and Aschoff [15] consider the amorphous form of cholesterin in the degenerated cells to be cholesteryl-oleate. They believe that the fatty acid unites with alkaline salts in the bile in the form of soluble soaps, and that there is a consequent precipitation of cholesterin. This view is based upon the refracting property of the amorphous globules. They are unable, however, to prove definitely that the amorphous bodies are chemically cholesteryl-oleate.

If the hypothesis of Adami and Aschoff proves correct, a most important question will be answered, viz., What initiates the primary precipitation of cholesterin crystals?

Baldwin [16] has shown that the desquamation of cells is considerable in infectious cholelithiasis and that cholesterin can be demonstrated in these desquamated cells.

Naunyn's hypothesis has been further strengthened by the experimental formation of gallstones, the experiments fulfilling as nearly as possible the laws he laid down. Thus experimentally,

gallstones have been produced in dogs, rabbits and guinea pigs by injecting an attenuated culture of typhoid or colon bacilli into the gall bladder after ligation of the cystic duct, or having placed a sterile foreign body in the gall bladder.

It was found that injections of virulent bacteria produced an acute cholecystitis without resulting gallstones, and that unless there was a stagnation of bile such as caused by a complete or partial obstruction, the bile quickly became sterile and no stones were formed. Foreign bodies were introduced aseptically, but these failed to produce stones unless accompanied by bacteria. Thus we see that stagnation of bile and a catarrh of the mucous membrane are two essential conditions in the formation of gallstones.

Calcium. — So far only the precipitation of cholesterin has been considered. It must be remembered, however, that calcium in conjunction with bile pigment enters largely into every gallstone. It is generally believed that calcium is produced by catarrhal inflammation of the mucous membrane of the bile ducts and gall bladder and precipitates about a nucleus. In every catarrhal inflammation there is an extrusion of albuminous matter from the inflamed membrane. Naunyn found that on adding egg albumin to bile there was an immediate precipitation of bilirubin calcium. Herter says, "The view expressed by Gilbert that the biliary calcium is largely derived from the mucous membrane of the gall bladder, through its mucous and desquamated epithelium, is probably in large part correct. . . . But, so far as I am aware, careful experimental data relating to the point are lacking."

Funke considers that "the weight of evidence seems to point to the fact that the salts contained within biliary concretions are largely a product of the mucous membrane. Baldwin found a marked increase in calcium in the fifteen cases of cholelithiasis which upon examination showed acid or neutral bile. He considers the acid as a probable factor in the calcium formation. This is diametrically opposed to Herter, who considers a superalkaline bile a possible cause. Bacmeister believes that the calcium is present in the mucus, which is enormously over-produced in the catarrhal conditions of cholelithiasis. The calcium, he believes, unites with the bilirubin of the bile and is precipitated about the cholesterin nucleus.

Rôle of bacteria in gallstone formation. — The question of bacteria *per se* as a cause has been carefully considered; that is, whether bacteria in the gall bladder do not act as a foreign body and initiate a precipitation of cholesterin. Thus Cushing [17] has advanced the theory that bacteria agglutinate in the gall bladder, thus forming a nucleus for precipitation. He has further demonstrated agglutination of typhoid bacilli, obtained from gall bladders, by serum of typhoid patients.

Richardson [18] found large clumps of typhoid bacilli in the gall bladder of five out of six cases of typhoid in autopsy.

Cantari [19] has found that the agglutinating power of bile in animals immunized against typhoid, colon and influenza bacilli is considerable, but not so great as is the blood serum.

Numerous investigators have examined gallstones for bacteria, both by culture and stain. Gilbert and Dominici [20] observed that bacteria were almost always demonstrable in recently formed calculi. Fournier [21] obtained growths from the nuclei of 47 out of 72 stones examined. Further work of a similar nature has been done by Pratt,[22] Gilbert and Fournier, Dufort, and Blumenthal. The most recent investigation is by Funke,[23] who examined 102 calculi by stain and culture. He obtained positive cultures in 31 stones. The bacteria found were B. typhosus, B. coli communis (these two formed the great majority), but also B. lumbatus, B. gasoformans, B. oxygenes, B. Friedländer, B. lact. aerogenes, B. tenacatis, B. subtilis. The wide variation of organisms is interesting, but it must be remembered that the finding of bacteria in gallstones is not of great etiological significance, since they may penetrate the stone from without.

The way in which bacteria reach the gall bladder has not been demonstrated. The possible modes of infection are four in number:

I. Direct from the peritoneum.

II. By the blood from the cystic artery.

III. By the common bile and cystic duct from the duodenum.

IV. In the bile from the liver by way of the portal circulation from the intestines.

Most recent authors believe that the last is the most probable route. In support of ascending infection from the duodenum, Bond [25] has shown that there are reverse currents in the intestines and that indigo-carmine particles have been carried from anus to gall bladder, and this mode of infection has been advocated by many. The work of Lartigau [26] and others in recent years has led to a reversal of opinion, and Mayo [27] in a recent article considers the portal circulation the probable mode of infection.

Hewlett,[28] in discussing the question, sums up as follows: "Adami and Ford have claimed that there is a constant passage of bacteria through the mucosa of the healthy intestines; and bacteria in the blood may be excreted in the bile (Cushing). The bacteria causing a cholecystitis are often not those commonly found in the duodenum. The infection of the biliary passages above a ligature around the common duct could hardly come from an ascending infection. Finally, if an enteritis be caused by the administration of arsenic, etc., and if the animal be fed some easily recognized organism, such as the B. prodigiosus, this organism can often be demonstrated in the bile passages."

Considering these hypotheses as a whole, the following would be a picture of gallstone formation.

Since hypotheses and the experimental evidence agree upon the stagnation of bile as the most important predisposing factor to gallstone formation, the first step in the sequence will be a stagnation of bile caused by one of a number of possible causes. Thus, the patient would have suffered from gastroptosis, pregnancy or some

condition mechanically hindering the free flow of bile; or, on the other hand, be a person of sedentary habits and chronic indigestion. While the above are the reasons usually given as the etiological factors of stagnation of bile, the mechanical problem seems more intricate than would be indicated by the general terms above mentioned. Further careful anatomical investigations should show some hitherto undemonstrated etiological factors.

In a large number of cases no preceding condition can be found except typhoid fever or chronic indigestion. So frequent is a history of indigestion with occasional pain obtainable in definite gallstone cases that it is quite possible that this is an etiological factor.

Since the contraction of the gall bladder is governed by a reflex established in the duodenum by the acid chyme, it is easily conceivable that a chronic catarrh of the stomach and duodenum might produce a reflex congestion of the mucous membrane of the gall bladder. As in a majority of cases of gallstone disease confined to the gall bladder, a sharp line of demarcation of the inflammation is observed at the opening of the cystic duct, it is probable that it is at this point, and not in the duct, that the obstruction occurs, through congestion and subsequent swelling of the mucous membrane. Such a congestion would not be caused by bacteria, but would afford a fertile field for bacterial infection through the bile. Apparently, there have been no experimental or autopsy findings to prove or disprove this theory.

An examination of the gall bladder in the pre-gallstone stage would show a somewhat enlarged bladder with a congested mucous membrane. The muscular coat would be rather atonic and thin from the infrequent contraction and interference with perfect circulation.

Examination of the contained bile would show desquamated epithelium containing some globules of amorphous cholesterin, these globules having been precipitated from the bile (Bacmeister) and reabsorbed by the cells (Aschoff) or being the product of the degeneration of the epithelium of the mucous membrane (Naunyn).

The bile would be sterile, but upon analysis would show an increased percentage of cholesterin and calcium, the former due either to the increased desquamation of epithelial cells or to some metabolic change in the body or liver, the latter due to epithelial desquamation and increased action of the mucous glands.

Such a gall bladder would give no symptoms. The next stage is that of beginning stone formation. In this stage the walls of the gall bladder probably remain as in the pre-gallstone stage. The contents, however, show a most interesting change. Detritus is much more evident in the bile. This consists of broken-down epithelial cells, held together by mucous, amorphous cholesterin (Bacmeister, Adami, Aschoff, Naunyn, etc.).

The exact chemical reaction by which these crystals are precipitated is still under dispute; according to Naunyn, they precipitate from the amorphous form by concentration; according to Adami, by the reaction of cholesteryl-oleate with alkaline bile salts; according to Kramer *et al.*, by an acid reaction of the bile which precipitates it from its union with the bile salts. The crystals have a tendency to unite, and gradually a small cholesterin stone develops. According to Bacmeister and Aschoff, this stone gradually increases in size by radial formation. According to Naunyn, the amorphous cholesterin forms a nucleus for the precipitation of bilirubin calcium which surrounds it. The bilirubin calcium is added layer by layer, but, while this is going on, amorphous cholesterin is infiltrating the stone from without through channels, and gradually replacing the bilirubin calcium, crystallizing out as pure cholesterin. In this way Naunyn believes the common mixed cholesterin-bilirubin-calcium stone is formed. In cases of pure cholesterin stone he believes the nucleus is encysted in a pocket of the mucous membrane and that the amorphous cholesterin gradually crystallizes about it, a stone thus forming. Bacmeister, as previously stated, has contrary views. Whether bacteria are present at the early stage of stone formation is another point upon which there is dispute; thus the upholders of the chemical hypothesis claim bacteria need not necessarily be present, but do undoubtedly accelerate the rapidity with which the stones form. The upholders of the mucous membrane hypothesis, on the other hand, claim that bacteria are absolutely necessary, and in experimental work no gallstones have been produced except in the presence of bacteria. It is necessary to conceive, therefore, that bacteria absorbed from the intestine are excreted in the bile, and that they lodge in the congested mucous membrane of the gall bladder. Here they establish a catarrh with an enormous increase in the mucous glands (Adolf Muller); with this there is an increase of mucus tending to cause a precipitation of calcium and a change of reaction of the bile, and increased necrosis and desquamation of epithelial cells, resulting in cholesterin formation.

The next stage is the stage of development of gallstones.

All the classical conditions for cholelithiasis are now present. The gall bladder, enlarged and relaxed, presents a chronic catarrhal inflammation of the mucous membrane, with atony and thinning of the muscular coat. It is filled with stagnant bile supersaturated with cholesterin and calcium. One or more stones in varying stages of formation may be seen. These stones are soft and readily take impressions from their neighbors and from the contractions of the gall bladder. The contraction occurs from time to time normally, as an effect of the inflammatory condition, or in an effort to expel the foreign bodies. A gradual increase in size and number of the stones takes place during this stage, and their presence accentuates the catarrhal condition of the mucous membrane. At any time the inflammation may become acute, due to a blocking of the already partially obliterated opening into the cystic duct, or to an increase in virulence of the bacteria.

Such exacerbations are more frequently the cause of pain than the passage of a stone into the cystic duct (Moynihan). In fact, most recent authors believe the pain of cholecystic gallstones is due to acute infection rather than mechanical passage of stones. An obstruction, interfering completely with the outflow of bile and consequent drainage of the gall bladder, however, may be due to a stone which acts like a ball-valve in the neck. In this condition there results a typical attack of colic lasting until the stone drops back into the bladder and drainage is again established. Thus at any time, the simple catarrh may change into an acute infectious cholecystitis with the resulting pathological changes. The consideration of the further increase in size and number of stones with the remarkable changes they may effect upon the gall bladder and other organs belongs to the realm of pathology and not to the pathogenesis of cholecystic gallstones.

A FALLACY IN PSYCHOTHERAPY.

"Fighting it Out" in Functional Nervous Disorders.

BY JOHN E. DONLEY, M.D.,

Physician for Nervous Diseases, St. Joseph's Hospital, Providence, R. I.

It is interesting to observe the gradual evolution of knowledge through which exact science comes to elucidate the facts of empirical observation. For centuries accomplished diners were convinced and acted upon their conviction that good appetite is a condition of good digestion; lately Professor Pawlow has proved that they were right. In another way, those who had much clinical experience of smallpox believed that red light was in some manner beneficial; within recent years we have learned that this is, in fact, the truth. And so it is in a large number of instances — the practical man is doing things aright long before the scientific man tells him the precise reasons for his action.

In the sphere of the mental life, saint and sinner have long since realized, and some of them have written it down in books, that spiritual conflicts within themselves are fraught with most disagreeable and, not seldom, disabling consequences. It has remained for abnormal psychology to show us somewhat of the mechanism of these conflicts and in some instances to assist us in preventing or removing their baneful effects. As determining our attitude toward functional nervous conditions, this more recent knowledge has contributed much, not perhaps as much as its more ardent disciples proclaim, but nevertheless sufficient to make our orientation within this nervous labyrinth a little more secure. We have learned, as the result of contemporary research, that possibly some of our common advice to patients has been based upon this or that psychological fallacy. Of one of these I desire to speak, namely, the fallacy of "fighting it out" in functional nervous disorders.

There is no occasion for surprise that where interest is so universal and the object of it so obscure, a multitude of opinions should be entertained concerning the true or best methods for treating various nervous affections. But if fallacies have crept in, they ought to be recognized, for fallacies are dangerous things; theoretically they may do no harm, but practically they are elements of discord which may disturb the otherwise harmonious course of our endeavors.

If we should happen to ask any one of our patients who at the time is troubled with what commonly goes by the name of nervous exhaustion, or hypochondria, or obsessions, or some form of depression, what he is doing about his many fears, anxieties and perplexities, he will inform us quite naturally that he is doing the best he can to "fight it out." That surely ought to be a brave thing to do, and so it is. But if we further inquire how he is succeeding in his fight, he will almost certainly tell us that things are not well with him, for otherwise he would not be consulting us at all. Despite his most determined efforts to bring the contest to some definite conclusion, nevertheless it seems well-nigh interminable. You will agree with me that there is no more pathetic spectacle than that presented by the man who has employed his time and his energy for months, perhaps for years, in this fruitless struggle, and has reaped as his reward nothing save discouragement and, in some cases, what looks suspiciously like despair. And yet I believe such a man may travel a road that leads to some measure, at least, of success.

By way of illustration let me ask you to indulge a quotation from Mr. Arthur Christopher Benson's suggestive volume, "The Altar Fire." Herein one may read:

"There is a story of a Cornish farmer who, returning home one dark and misty night, struck across the moorland, every yard of which he knew, in order to avoid a long tramp by road. In one place there were a number of disused mine-shafts, — the railing which had once protected them had rotted away, and it had been no one's business to see that it was renewed, some few had been filled up, but many of them were hundreds

of feet deep and entirely unguarded. The farmer first missed the track and after long wandering found himself at last among the shafts. He sat down, knowing the extreme danger of his situation, and resolved to wait till the morning, but it became so cold that he dared stay no longer for fear of being frozen alive, and with infinite precautions he tried to make his way out of the dangerous region, following the downward slope of the ground. In spite, however, of all his care, he found suddenly, on putting his foot down, that he was on the edge of a shaft and that his foot was dangling in vacancy. He threw himself backwards, but too late, and he slid down several feet, grasping at the grass and heather; his foot fortunately struck against a large stone, which, though precariously poised, arrested his fall, and he hung there for some hours in mortal anguish, not daring to move, clinging to a tuft of heather, shouting at intervals, in the hope that, when he did not return home, a search party might be sent out to look for him. At last he heard, to his intense relief, the sound of voices calling him, and presently the glare of lanterns shot through the mist. He uttered agonizing cries and the rescuers were soon at his side, when he found that he had been lying in a shaft which had been filled up and that the firm ground was about a foot below him, and that, in fact, if the stone that supported him had given way, he would have been spared a long period of almost intolerable horror."

Now in this Cornish farmer we have a striking example of what I shall call the pugnacious attitude, the attitude, namely, which impels to an active campaign, inasmuch as it leads its adherents to "hold on," and, in the case of nervous people, constantly to try conclusions with their abnormal mental states. Let us approach this attitude somewhat critically and endeavor to determine its practical value. It will not be denied that the first step in the direction of nervous instability is introspective analysis, and Ribot is right when he remarks: "The healthy, normal man suffers himself to live physically and morally without studying himself and without watching himself live, at least any more than is necessary. But the moment the demon of analysis has entered into us, we do not know where it may lead us; an absolute tyrant, it will one day remain sole master of the place. Even under its feeble form it is the first stage in morbid evolution. The inevitable outcome of this tendency to analysis, so soon as it has passed a certain point, is mental disaggregation. The majority of people, either by strength or by feebleness of intellect, by luck or ill-luck, by a simple and limited life or by incapacity of attention to maintain it, escape this tendency. But if there are many who escape the ill-effects of mental analysis, there are also many who suffer seriously from the wounds this tendency inflicts." Among those who suffer most intensely are nervous people, the evil genius of whose existence is a morbid subjectivism. Every typical neurotic is so constantly and, I was going to say, so exclusively interested in the manner of his living that he suffers a corresponding contraction of interest in life itself. Such a man does not — it is too much to say that he cannot — read without considering whether it is going to fatigue his brain; he eats nothing without watching the process of digestion; if he takes a walk he fears he will overfatigue himself; bathing fills him with the apprehension of catching cold; in bed he is forever listening for his heart-beat, and when about during the day his finger is frequently feeling for his pulse; in a word, he does nothing without a magnified self-consciousness. Here, if there be such a thing, is a truly exaggerated ego. So contracted has his mental horizon become, so atrophied his interest in everything except his own sensations, and so pessimistic his outlook upon life, that he actually ceases to be a useful member of society, and becomes a burden to himself if not to his friends as well. He has replaced the extra-spection of normal living by the intro-spection of neuroticism.

Now to advise, or even to permit, a man of this temperament to "fight" his condition, which is simply another way of inviting him to continue his morbid intro-spection, seems very much like requesting the moth to get into the flame. For if we are to have a genuine fight, assuredly we must have some place to fight and some one to do the fighting. In this particular instance the battle-ground must, of necessity, be within the mind of the patient, and the contestants, his will on one side and his emotions on the other, with his intellect wavering in its allegiance, inclining now to one side and now to the other. And remember, this can be no half-hearted contest, — there is too much at stake; it must theoretically be a fight to the finish, only practically the weary patient finds that for him, at any rate, there is no finish, and that after weeks, months, years, perhaps, of struggle, he is but going round and round like a squirrel in a cage, while his strength and, more especially, his courage have suffered undesirable depletion. I have known a young man, holding a position of trust in a banking house, who left his employment and his very young family on account of a moderate nerve exhaustion, which was accompanied by the usual depression and morbid fears, and who went into the woods of Maine for the purpose of "fighting it out," because he had several times been strongly advised that such, no doubt, was the proper method to pursue. In four months he returned worse than before, and virtually a slave to his magnified fears and abnormal sensations. It cannot turn out otherwise on the pugnacious principle, for is not the primary psychological difficulty a morbid subjectivism? And what is "fighting it out" but a continuous, systematic, deliberate perpetuation of this same subjectivism? since, obviously, one cannot fight something unless one is conscious of it, sets it before the mind and keeps the attention more or less fixed upon it. To fight is to hold on; it is to cling in desperation, as the Cornish farmer did, to the mental grass and heather, with the solid earth only a foot beneath.

The plausibility of the pugnacious attitude receives a certain confirmation from the rugged

reasoning of the man in the street, but it is not difficult to show that this reasoning is vitiated by a fallacy, namely, the inveterate fallacy of picture-thinking, by which I mean the universal habit of describing things of the mind in terms of physical objects of sense, and then mistaking such descriptions for mental realities. We all do it, but that is precisely why we should be on our guard against it. The fighting attitude has arisen in some such way as this: If my neighbor Jones annoys me by trespassing upon my private grounds and shooting my game, it is entirely possible for me to terminate this annoying situation by the primitive method of a fight with Jones, during which fight I may put an end to his physical ability to trespass again upon my land. The matter is settled once and for all by the physical elimination of Jones. But observe now what happens when the attempt is unconsciously made to apply this reasoning to processes within the mind of a neurotic person. The analogy, like many another analogy, cannot be made to fit. The morbid ideas and fears which annoy my patient by their intrusion upon the course of his thoughts are not physical things, to be dealt with by the summary method of annihilation, for it is impossible *directly* to strangle or shoot or punch an idea out of existence. So impalpable are they, so elusive and so tenacious of life, that, even when apparently banished for good, they have a disagreeable habit of turning up again at the most inopportune times and in the most trying situations. And accordingly, even though the patient may have fought and have been awarded a prize upon numerous occasions, the contest is by no means ended; the same fruitless, dreary fight must be continued as often as a rebel thought gives him challenge. But it may be objected, while this is all very well and even, in its way, quite plausible, still it is more or less reasoning *a priori* and may have no foundation in actual fact. Well, then, let us observe what experimental psychology has to say in the matter. Through a number of valuable and, in some sense, epoch-making researches, carried on within recent years, we have come into possession of a vastly more comprehensive knowledge of the factors at work in the production and maintenance of different states of psychological instability. It is perfectly true that there are large and serious lacunæ in our knowledge, but sufficient headway has already been made to enable us more intelligently to steer our course in the treatment of many nervous disorders.

Some of the most valuable and quite the most illuminating of this work we owe to Dr. C. G. Jung, of Zürich, whose researches into the problems of association have opened an entirely new and, let us hope, fertile field to students of mental life. Experimenting with a considerable number of persons, Jung discovered that there are certain associations of ideas which liberate a marked emotional wave, and certain others which produce little or none. The experiment is carried out in this fashion: I announce to you, one by one, a series of words, forty-five or fifty, for example, and request you to speak out immediately the first word, which stands, of course, for the associated idea, that arises in your mind. This is your association for the particular word given you. By means of a stop-watch I measure the time that elapses between the moment of my announcing the test word and your speaking the associated word, this time being termed your reaction-time. Now it has been found that for ordinary words, not specially significant, each individual has an average reaction-time, which varies within moderate limits. The following is the abridged record of an experiment to determine average reaction-time:

Stimulus word.	Reaction word.	Reaction-time. Seconds.
Book.	Poems.	1.5
Bridge.	Water.	1.3
Man.	Father.	1.4
Winter.	Snow.	2.0
Food.	Bread.	1.2
To walk.	Country.	2.1
City.	Providence.	1.0
Hat.	Derby.	1.4
Rubbers.	Rain.	1.5
Flowers.	Roses.	2.0

The average reaction-time for fifty words was 1.4 seconds.

Having determined the average reaction-time for this particular individual, let us now study another series of associations with the same individual.

Stimulus word.	Reaction word.	Reaction-time. Seconds.
Bird.	Poe's Raven	1.4
Woman.	Mother.	1.7
Sleep.	Dream.	5.2
College.	Yale.	1.2
Star.	Comet.	7.0
Country.	Cows.	1.8
Paper.	News.	6.5
Philosophy.	Zeno.	1.3
To swim.	River.	1.5
Astronomy.	Telescope.	1.6

Here, it will be observed, were three lengthened reaction-times: Sleep, dream, 5.2; star, comet, 7.0; paper, news, 6.5. What do these signify? According to Dr. Jung and his followers, they mean that the association of ideas aroused by the stimulus word was of such personal and significant interest to that individual as to give rise to an accompanying emotional state which interfered with the rapidity of association, which blocked it, as it were, and caused a lengthening of the reaction-time. Lengthened reaction-time means, therefore, the presence of some disturbing emotion.

Upon inquiry I was interested to learn that the cause of the above lengthened reaction-times was this: The young man, having read an account of comets in a popular magazine, became obsessed by the idea that a *comet* was likely to strike the earth and to cause enormous damage. He had experienced a very vivid *dream* about it, and was continually apprehensive that at almost any time he might read in the *newspaper* an account of the comet's having actually fallen. Accordingly, when the ideas, "sleep," "star," "paper," were presented to him, they aroused emotional states which obstructed the customary and equable

flow of his mental processes and gave rise to a certain degree of psychological instability. During a course of psychotherapy the disturbing emotional complexes were removed, and when this had been accomplished the obsessions disappeared completely. Three years have passed and they have not returned. Doubtless these subconscious emotions will in the future prove to be most important elements in the composition of various nervous disorders. And incidentally it may be of interest to remark that by means of the lengthened reaction-times for certain of their associations, some criminals have been detected and have confessed to crimes which previously they had denied before being confronted with the evidence obtained through the methods of experimental psychology.

More interesting, perhaps, than even the associations themselves are the changes in the electrical resistance of the body during the formation of an association carrying with it a distinct emotional load. This phenomenon is known to psychologists as the psycho-physical galvanic reflex. A constant current from one or two cells is allowed to pass through the body by way of the hands or feet, which rest upon large copper plates, and in the circuit of this current is arranged a mirror galvanometer of Deprez-D'Arsonval for the purpose of measuring the quantity of current flow. By means of an ingenious device the variations of the current-flow are registered by a recording pen upon a revolving drum, and hence it is possible to keep a record of the variations of electrical body resistance for a considerable period of time, the record appearing as a tracing marked by the pen upon the paper surrounding the drum.

Let us assume that, with everything arranged for the experiment, we throw on the current and observe what occurs. While the subject of the experiment sits quietly and breathes easily we notice that the quantity of current passing through his body oscillates slightly about a certain mean. Suppose, now, that we announce to him a word which will arouse an association with a personal interest; what will happen? Immediately, or very shortly, the galvanometer will indicate that more current is passing through his body, while the recording pen will trace on the drum a deep oscillation to accord with the altered current flow. In this manner we may demonstrate to the satisfaction of any one that a mere word which sets off an emotion produces a perfectly measurable electrical change; and, however remarkable it may seem, it is none the less a scientific fact that a simple word is so potent as to lower the electrical resistance of our bodies.

My purpose in thus briefly describing these interesting experiments is to show the profound influence of certain associations of ideas upon our emotional stability. If, then, it is demonstrably true that simply to inaugurate a disagreeable emotional complex is sufficient to produce some degree of nervous instability, it would seem but a logical extension of the argument to maintain that the constant stimulation of such complexes in the process of "fighting it out" is a psychological blunder. I know of no experiments of the sort, but were it possible to test the galvanic reflex while a nervous person was actually in the process of "fighting" his condition, it is not unreasonable to suppose that positive changes in the organism would be brought to light. And such changes would scarcely be conducive to mental and physical stability.

Against the militant attitude a further objection may be raised. Utilizing the method originated by Pierre Janet, and further elaborated by Breuer and Freud, we have learned that the effort to crowd out of mind, to suppress, the memory of a disagreeable experience or set of experiences, in a word, to "forget it," is oftentimes the source of troublesome nervous disorders. A young girl, for example, because of her attempts to smother the memory of a disagreeable experience, may find herself later on the victim of a severe attack of hysteria with all its mental and physical disabilities. And not until this smothered experience has been brought out into the light, not until it has been somehow assimilated, will such a girl return to her former health of mind and body. A greater or lesser degree of nervous instability is the price we pay for trying to smother and to forget our unacceptable experiences.

That this is not extraordinary any one may prove out of his own personal experience. There is scarcely one of us, I suppose, who has not at different times endeavored by main force of will to crowd out of mind some disagreeable experience of the past, some anxiety or sorrow or fear, and in so doing has been conscious mainly of two things: first, the absolute futility of the effort; and, second, its disturbing influence upon tranquility of mind. We have not only not succeeded in our struggle, but we have made a bad matter worse. And if this is true of normal individuals, how much more true must it be of those who are nervously unstable, who have not the toughness of moral fiber to withstand this constant struggle with its interminable failures, and whose physical and mental salvation is imperiled through no fault of their own, but because of the fundamental inadequacy of their method. To maintain a state of conflict within one's own mind is to prevent that unselfconsciousness so essential to mental health.

Most strikingly is this illustrated in the case of the religious consciousness. For those who have passed through personal religious crises, which represent some of the most intense intellectual and especially emotional experiences, the fierce struggle within their souls has been a most fruitful source of discontent, unhappiness and even, at times, of misery. A correspondent of the late Prof. William James writes the following statement: "Life seemed difficult to me at one time. I was always breaking down, and had several attacks of what is called nervous prostration, with terrible insomnia, being on the verge of insanity, besides having many other troubles, especially of the digestive organs. I had been sent away from home in charge of doctors, had taken all the

narcotics, stopped all work, been fed up, and, in fact, knew all the doctors within reach. But I never recovered permanently until this New Thought took possession of me. I think that the one thing which impressed me most was learning the fact that we must be in absolutely constant relation or mental touch (this word is to me very expressive) with that essence of life which permeates all and which we call God."

Here, then, was a woman who, having tried the pugnacious method without avail, finally surrendered, and, by giving up, came into possession not of spiritual riches merely, but of nervous health as well. I have no intention, of course, to convey the idea that in every case an appeal should be made to the religious consciousness; I wish merely to elucidate a principle. When, however, religion is a living force in the life of an individual, I see good reasons why it should become a means of emancipation from the slavery of many fallacious thoughts and morbid emotions.

The power of the religious idea as a psychological aid toward terminating the fighting attitude may be illustrated by a further example. A young woman, following a severe railroad accident, had become practically a prisoner in her own home because of an ever-present fear of going upon the street. Every sort of effort and appeal had been made without success until one day the pastor of her church called to see her and produced a somewhat unexpected result. During his visit the clergyman conversed with her about her unhappy condition, and, during the conversation, he asked her whether or not she professed to be a Christian, to which she gave an affirmative answer. "My dear young woman," replied her friend, "you aren't a Christian at all; you are a pagan. You ask me why. Well, I will tell you plainly. Look out of the window and behold the sun, and the trees, and the flowers, and the birds — all of these things were made by God for the comfort and happiness of his creatures. He made them for me and for you, and yet you who so ardently profess to be a Christian, who pray, and pretend to believe in the protecting Providence of God, are afraid, literally afraid, to trust your God; you are afraid to go out of this house which God gave you, into the street which God made, too. I say that whatever you may profess on your lips, in your heart you are a pagan!" So powerful was the leaven of these words, in this instance, that in not more than two weeks from the time they were spoken the young woman had given up "fighting it out," and, by letting go, had won a complete victory over her fears. I do not know whether they ever returned.

But aside from religion, this same attitude of surrender may be attained through an appeal to a commonsense philosophy, such philosophy, for example, as sustained Epictetus, and Marcus Aurelius, and Seneca in his letters to Lucilius. It is not so much drugs that many nervous people need; it is a practicable philosophy of life, — one that will enable them to enter more courageously the dusty arena where men and women are fighting the perplexing problems of life. Many nervous people have been nurtured, unconsciously, no doubt, to a certain effeminacy of emotion. They require to be always comfortable and to have their feelings swathed, as it were, in cotton. A certain amount of worry is inseparable from any active life; to accept such worry philosophically is worth more than all the efforts in the world to banish it by trying to "fight it out." Practical psychotherapy, whether it employ suggestion, persuasion, psycho-analysis, hypnoidization or other procedure to compass its purposes, has always in view the removal of inner conflicts which harass the harmony of normal existence.

"This attitude of surrender is all very ideal and very utopian; it belongs to the class of things that are important, if true," some one may say. "But the plain, stubborn, everyday fact is that these unhappy neurotics would all surrender, they would all let go, if they could, but, as it happens, they cannot." Here, then, we come upon the very root of the whole matter. The nervous person says, "I cannot let go," which, more accurately stated, would be, "I do not let go because I have never been taught how to do it."

In order that we may put this idea of surrender to what the late Professor James would call "a pragmatic test," let us return to our Cornish farmer and inquire how the hypothesis actually "works." You will remember that this unfortunate man kept clinging in absolute horror to the grass and the heather until a certain point of time, — that moment, namely, when the rescuers arrived to lend their assistance. You recall also that the occasion of his clinging at all was the fact that because of the intense darkness he could not *see*, and, therefore, did not *know*, that the firm ground was but one foot beneath. When the light of his rescuers' lanterns disclosed it to him, like a sensible man he let go and went home, although, left to himself, he would have continued to hold on as long as his strength endured.

Now the predicament of this poor farmer is precisely analogous to that of the average nervous man or woman. The farmer was in darkness, which meant ignorance; so, likewise, is the neurotic, because of his lack of knowledge of the true meaning and value of his myriad morbid ideas, sensations and emotions. Like the farmer who, without knowing, assumed an empty shaft, he assumes a catastrophe in every symptom, and in his efforts to crowd his fear out of mind, to "fight it down" and to keep the lid upon it, he succeeds merely in setting up within himself a constant turmoil of anxiety and depression. Left to himself, he can do little or nothing to solve the recurring riddle.

It is here, I believe, that the trained and sympathetic physician finds the opportunity of his greatest usefulness and becomes a practical necessity. He should be a man who brings the light, who can mediate between science and life; and as the farmer put his foot upon solid ground when the lanterns of his rescuers allowed him to see that it was really there, just so many a nervous sufferer will relax his hold upon his fears when his

physician reveals to him the truth which here as elsewhere shall set him free. When his errors of fact and especially of inference have been pointed out to him, the neurotic, so far as I have seen him, assumes the "will to believe." The problem, then, takes the complexion of educating him out of the habit of fight into one of surrender; a surrender, be it carefully noted, based not upon a mere dogged effort of will, but upon *knowledge* which is power, and which discloses the complete futility of the contest. Not always, indeed seldom, is it an easy task, this metamorphosis of a man's personality, but when it is pursued with intelligence and persistence, it is certain to attain to some degree of success. It is assumed that the Cornish farmer felt stiffness and perhaps some pain in his arms for days as the result of his clinging to the grass and the heather; and in neurotic people it is expecting too much of them to suppose that they will feel no trace of the fight, even if they have surrendered. Not all patients respond to treatment of this or of any sort; nor can we physicians altogether prevent the onset of future fears and anxieties which will take the place of those we have helped to banish, for it is much as Francis Thompson says,

> "Nothing begins, and nothing ends,
> That is not paid with moan;
> For we are born in other's pain,
> And perish in our own."

SPONTANEOUS DISLOCATION OF THE HIP-JOINT FOLLOWING ACUTE INFECTIOUS DISEASES.*

BY CHARLES GREENE CUMSTON, M.D., BOSTON.

SPONTANEOUS dislocation is an infrequent sequel of various infectious processes, but of all the joints in which this can take place, that of the hip is certainly most common.

This complication has been known for a long time, but it has only been examined scientifically within the last twenty-five years. In 1722 the famous J. L. Petit published his important work on dislocations, in which he endeavored to prove the theory of hydrops as the causative factor for the dislocation. In 1835, Parise upheld the conclusions arrived at by Petit, over a hundred years before, by means of experimental work on the cadaver. A number of other writings were published, so that Helwig, in 1856, was able to collect twelve cases of post-typhoidal dislocations. One year later, Roser published an exhaustive study, and since then much attention has been given to the question, and many cases have been put on record. Keen collected thirty instances of post-typhoidal dislocation in 1877, while in 1883, Verneuil drew attention to the part played by the muscles in the production of dislocation from a study of several cases of post-rheumatic luxation. The most extensive articles which have appeared on the subject are due to Kummer, who collected fifty-one instances, and Degez, who compiled seventy-four cases of spontaneous dislocation of the hip-joint. Very little attention has been given to the subject in the recent treatises on surgery, so little, in fact, that even in Keen's Surgery, in five volumes, only about a page is devoted to spontaneous dislocations in general and nothing to that of the hip in particular.

The following is the history of a case recently under my observation.

J. H. W., nine years of age, female, had a rather severe scarlet fever in March, 1910. She had always been a healthy child, her locomotor system being perfectly developed. She had never been ill since birth until the scarlet fever. She was in bed for six weeks and finally convalesced, there being no visceral complications. When she began to walk, in the latter part of May, it was noticed that she had a decided limp and that the right leg was considerably shorter than its fellow.

We saw the patient on May 27, at which time the following notes were made: The patient was a well-developed girl, with excellent muscular development. Careful examination of the thorax and abdomen, likewise the urine, was absolutely negative. By measurement, the right leg was found 4 cm. shorter than the left; it was in marked adduction, with internal rotation, which caused the patient to walk with marked limping. The motions of the right hip-joint were considerably interfered with, rotation and flexion being almost entirely absent. The trochanter major was found 4 cm. above the Roser-Nélaton line. There was no pain on pressure, nor were there any other objective symptoms, so that a diagnosis of iliac dislocation of the femur following scarlet fever was made.

Extension, in order to reduce the shortening and to improve the position of the limb, was first resorted to and carried out for five weeks, but as little or no improvement resulted, it was decided to attempt reduction of the dislocation under narcosis, which was done on July 3. After considerable manipulation the head of the femur was made to enter the acetabulum and the reduction was found to be complete. A plaster cast was applied, the limb being placed in abduction, with extension. The extension was kept up until Aug. 17, at which time the cast was removed, when, other than the muscular atrophy, the joint was found in good condition. Electricity and massage completed the cure, so that at present (Sept. 2) the patient is quite well, the functions of the limb being perfectly restored.

In discussing the etiology it is striking how frequently the hip-joint is the seat of spontaneous dislocation, and out of eighty cases collected by Degez, the hip-joint was involved seventy-four times, the shoulder three times, the knee twice and the elbow only once. Perhaps this frequency may be in some way due to the youth of the patients, because it is well known that the hip-joint has a great tendency to the development of pathologic processes in early life, and of ninety cases which I have been able to gather, in only eleven was the patient over twenty years of age. The type of dislocation was iliac eighty times, obturator dislocation six times and perineal dislocation once.

By far the most important causal factors for the development of spontaneous dislocation are typhoid fever and acute articular rheumatism. Then, in order of frequency, come scarlet fever, influenza, smallpox, gonorrhea, erysipelas and

* Presented at the Sixth French Congress of Gynecology and Pediatry, Toulouse, France, Sept. 22-27, 1910.

puerperal fever. In a few instances the causal factor could not be ascertained with certainty. In the cases I have collected the causal factor was as follows: Typhoid fever 34, acute articular rheumatism 28, scarlet fever 15, influenza 4, smallpox 3, gonorrhea 2, erysipelas and puerperal fever, of each 1, while in three others the cause was not determined.

The dislocation usually takes place during convalescence and is particularly apparent in typhoid fever, while in acute articular rheumatism and scarlet fever the complication is prone to occur during the progress of the disease.

Although there is no doubt as to the relationship between spontaneous dislocation of the hip and acute infectious diseases, the mechanism of its development is as yet insufficiently explained. The pathogenesis of spontaneous dislocation has always been rather a puzzle, and for this reason there are several theories which are more or less logical. Petit's theory, advanced in his work already referred to at the commencement of this paper, is that all spontaneous dislocations arise from an effusion of fluid into the cavity of the joint. He believed that the capsule became distended on account of the intra-articular fluid, that the ligaments became softened and lax, and that the head of the bone was pushed from the joint cavity on account of the hydrops and thus resulted in dislocation. This theory was supported by the experimental work of Parise, who injected liquid into the hip-joint of cadavers, and the same result was invariably attained, namely, that great distention of the capsule, with a posterior dislocation, took place. Parise, therefore, came to the conclusion that the structures of union of the joint became lax to such an extent from stretching of the ligaments that the head could be forced out of the acetabulum.

Roser agrees with this theory, which he tries to prove by pointing out that there is no evidence of either acute or chronic inflammatory processes in the cavity of the joint, and also because, in the reported cases, there is no history of trauma or blood extravasation. He, therefore, concludes that the only explanation for spontaneous dislocation is an intra-articular fluid collection causing marked distention of the capsule. Now, in point of fact, in quite a number of cases a hydrarthrosis has been found at operation, and from this there had resulted a distention and softening of the capsule, with separation of the head of the femur from the acetabulum.

It is easy to conceive that the effusion is important for the occurrence of the dislocation, and it is hard to understand why some writers have attributed the ability of preventing dislocation to this effusion. Whether or not hydrops of the joint is alone sufficient to explain the production of a dislocation is rather doubtful. Kummer is of the opinion that the fluid can at most force the head of the femur to the rim of the acetabulum, and in order to force it over the rim he believes that there must be some other external influence, slight as it may be. He also points out that the amount of fluid contained in the joint is so small that it can hardly be the only causal factor in the production of the lesion.

Verneuil and Reclus endeavored to explain the occurrence of spontaneous dislocation by abnormal muscular contraction with paralysis and atrophy of the antagonists. In iliac dislocation particularly, they attributed the following mechanism: Before the dislocation takes place the leg is in a position of flexion and adduction, so that the resistance of the acetabulum is very greatly diminished. The structures which especially tend to prevent the exit of the femoral head from the acetabulum are the capsule and the muscles. If the former becomes stretched and relaxed, and if the pelvi-trochanteric muscles lose their tone by atrophy, the contraction of the antagonistic adductors can raise the head over the rim. Therefore, three factors must be combined in order to produce a spontaneous dislocation, namely, (1) a bad position of the limb, particularly favoring the functions of a group of muscles; (2) atrophy and paralysis of the antagonist; and (3) relaxation of the capsule and ligaments. This theory, however, is not satisfactory because there usually must also be some external cause in order to produce a dislocation. Then there are those cases which would be very hard to explain by the muscular theory, in which iliac dislocation does not occur and instead an obturator position is found.

Graff has called attention to the obliquity of the upper rim of the acetabulum as a possible explanation for the development of the spontaneous dislocation, and he also emits the opinion that there may, possibly, be a congenital tendency. Possibly the obliquity may be the result of a slight intra-articular inflammatory process, and Roser has mentioned the occurrence of pressure atrophy occurring on the posterior rim of the acetabulum as a result of incorrect positions of the limb, but he has only considered this as an etiological factor in a few cases. Graff, contrary to Roser, basing his assertion on a number of cases which he personally observed, considers the obliqueness of the roof of the acetabulum as characteristic in all cases of spontaneous dislocation, and believes that its mechanism may be explained from this anatomic change.

It has already been pointed out that, besides these predisposing factors, the nature of which has given rise to much difference of opinion, only a relatively slight trauma is necessary to produce dislocation, and there are numerous recorded cases to demonstrate this fact. In Capelle's case the dislocation occurred during the transportation of the patient from one bed to another, and this has been observed by several other competent observers. It would seem to me that Kummer has very appropriately summarized the pathogenesis of spontaneous dislocation of the hip in a few words, namely: "Secondary dislocation, although being prepared by internal causes, requires, just as in ordinary traumatic dislocation, the production of some violence as an effective cause, and the pathogenic difference principally resides in the degree of the latter."

The study of the pathologic changes has of

late made considerable progress, as they have been directly studied at autopsy. These changes refer to the ligaments, the joint and its contents, the surfaces of the joint and the muscular structures. In contrast to traumatic dislocation, in which there is always rupture of the capsule, in a spontaneous type there are only slight changes present in the joint ligaments. In most instances there is only softening and distention of the capsule, while it may also present some increase in thickness. In several recorded cases there was a marked thickening of the anterior wall of the capsule, while in another case the increase in thickness was found on the posterior wall, and the ligamentum teres was stretched. Besides these slight changes there are some recorded cases in which it would appear that rupture had taken place, likewise that of the ligamentum teres, and in one case where the lesion was due to gonorrhea almost the entire ligamentum teres was destroyed. No trace of either the capsule or the ligament could be found by Payr at operation for a post-rheumatic dislocation.

The nature of the contents of the joints has been the cause of much discussion. Hueter believes that all spontaneous dislocations of the hip-joint are due to the presence of a purulent infection, and his opinion has been upheld by Weil and Voelkel because they found pus in the joint of a post-typhoidal dislocation. I am only aware of one other similar case, this being published by Bonnet. In all other cases where a collection was found, it was either serous or serofibrinous. The question has also been much discussed as to whether or not an inflammatory process in the joint occurring during acute infectious diseases is or is not caused by the specific organism of the disease. The question is not settled, but a case recorded by Graff is interesting in this respect. It was that of a patient with a post-typhoidal hip-joint dislocation in which an abscess burrowed to the surface in the adductor region eighteen months after the typhoid, and in the pus the living typhoid bacillus was demonstrated beyond a doubt.

The joint surfaces are, on the whole, only slightly changed, and in many cases they have been found apparently normal. Other cases have been met with in which cartilaginous outgrowths on the head of the femur were found during arthrotomy, in a case of post-rheumatismal dislocation by Lücke; Eisendraht found the cartilaginous covering of the acetabulum eroded, while in Degez's case there were cartilaginous bodies on the head of the femur and in the posterior upper portion of the glenoid cavity. In all these instances the head of the femur had retained its normal shape and was of firm consistency. There are also a number of other cases in which a marked overgrowth of cartilage was found. In Payr's case the femoral head was atrophied and covered with hard excrescences and was connected with the ilium by a typical nearthrosis. The latter presented a comb-shaped ridge of bone from two to three centimeters in height.

If the dislocation is not soon reduced, connective tissue will soon fill up the glenoid cavity, and many such cases have been recorded. Then, again, sloping and flattening of the upper rim of the acetabulum may occur. Muscular atrophy and contraction have been found in a number of operations, and Kummer found the greater gluteal muscle as thin as paper. In these cases the contraction first affects the adductors. This may be either a reflex contraction, disappearing in narcosis, or it may be of organic nature, and can only be corrected by tenotomy. In one of Graff's cases the muscles were partially ossified.

We may thus briefly summarize the most important pathologic changes occurring in spontaneous dislocation of the hip as follows: (1) Comparatively slight changes in the joint, especially over the femoral head; slight cartilaginous outgrowths in the glenoid cavity; (2) connective tissue overgrowth in the glenoid cavity; (3) sloping or flattening of the roof of the acetabulum; (4) muscular atrophy with contraction of the antagonists.

The symptoms of spontaneous dislocation of the hip are quite the same as in the traumatic type, namely, disturbances of function, displacement of the trochanter major, a depression in the normal region of the femoral head, the latter being found in an abnormal place. Pain is particularly evident in the post-rheumatismal form, a fact that has been denied by certain observers. Kummer had one case of post-rheumatismal dislocation in which there was a sudden and great increase in pain when the dislocation took place, but, nevertheless, too much reliance must not be placed on this symptom, as it may be wanting. What is more characteristic of spontaneous dislocation is that the lesion is first discovered only when the patient resumes walking. Of course, in doubtful cases the x-ray is to be used.

The prognosis depends upon the length of time the dislocation has existed, because when discovered early it may frequently be reduced, otherwise this is with difficulty accomplished, or even not at all. The inability to reduce the dislocation is due to the pathologic changes which have taken place, especially nearthrosis and ankylosis of the head, filling up of the glenoid cavity with fibrous tissue, and atrophy and contraction of the muscles. It is probable that these various changes do not take place as rapidly in the spontaneous as in traumatic dislocation, because in the former the irritative process due to the trauma are lacking. Consequently, for this reason the prognosis of the spontaneous type may possibly be somewhat better than in the traumatic form. It should be pointed out, however, that in some cases of spontaneous dislocation reduction could not be accomplished two months later, whereas Dittel was able to successfully reduce the femur in his case five months after the dislocation had occurred. Schoemacker has published a case where, after thirteen years, he successfully reduced a spontaneous hip dislocation without being obliged to resort to operative measures.

The treatment should, of course, in the first

place be preventive, but on account of the great infrequency of this complication it would certainly be unnecessary to be on the watch for its occurrence in every case of acute infectious disease. On the other hand, particularly when there has been a faulty position of the limb for any length of time, particularly in typhoid, acute articular rheumatism and scarlet fever, one should always bear in mind the possibility of the occurrence of this complication, and, therefore, at the time the patient is about to leave his bed it should be searched for. If during the course or convalescence from a case of typhoid or scarlet fever a permanent flexion or adduction occurs, one should certainly ascertain if this complication has arisen, and if it has not, by placing the limb in a correct position a dislocation will undoubtedly be avoided. Extension, with slight abduction, will prove of value.

Regarding the treatment of the dislocation, the principal aims to be obtained are, first, to reduce the dislocation if possible, and, secondly, if this is an impossibility, to transform the bad position of the limb into a functionally useful one. Two methods are at our disposal, namely, the bloodless and the operative. As has already been pointed out, the pathologic changes which prevent reduction occur relatively late in spontaneous dislocation and, for this reason, the femur may be reduced in many cases quite a long time after the dislocation has taken place. The attempt at reduction should be preceded by first mobilizing the femoral head by movements of rotation and putting the soft structures on a stretch. Reduction must be done slowly and without too much force because otherwise extravasation of blood may result. The various methods for bloodless reduction are so numerous that it is quite impossible to discuss them here, but, in a general way, they are the same as those employed in the traumatic type. It has been generally found that the sudden, snapping sound which is heard when the head enters the glenoid cavity in reducing a traumatic dislocation does not occur in the spontaneous type. In the latter, it is a soft sound as if the head had sunk into soft wax or butter.

If the reduction has been successful, it is of the greatest importance to prevent a recurrence, because in fourteen of the recorded cases this has taken place, and in four of them it could not be reduced the second time. The best measure to be employed for avoiding a recurrence is a plaster cast with the limb in abduction and extension, and it is very important that the plaster be not removed too soon. If the bloodless reduction is not successful, or if it is impossible to hold the head in the acetabulum, one may then resort to extension, which in some cases has brought about a marked functional improvement. Nevertheless, the extension should not be continued too long because it might result in a lax nearthrosis. By extension the shortening will be temporarily diminished, but when the patient starts to walk again it may be greater than before treatment. It should also be mentioned that the so-called forward transposition was recommended by Ollier, and more recently by Goldmann. This consists in changing a posterior dislocation into an anterior one in order to obtain a nearthrosis on the anterior border of the ilium. This procedure has as yet not been resorted to in spontaneous dislocation, so far as I know, but in the traumatic type good functional results have been reported.

If the bloodless treatment remains unsuccessful, operative treatment must be resorted to. It is of highest importance never to undertake operative treatment immediately after attempts at bloodless reduction have been tried. From the crushing of the soft structures as the result of attempts at forcible reduction, the prognosis of operative interference is rendered rather bad and, therefore, it is better to postpone the operation for about a month.

We have three operative interferences at our disposal for the reduction of spontaneous dislocation of the hip, namely, (1) operative reduction; (2) resection; and (3) subtrochanteric osteotomy.

Theoretically the operative reduction is certainly to be looked upon as the most logical procedure of the three methods, for the simple reason that it restores the parts to a normal condition. However, there are some points to be considered in this operation which places a somewhat limited value on it. In the first place, operative reduction is, without any doubt, a difficult operation and should only be resorted to in strong and healthy subjects. Then again, the ultimate functional results are by no means brilliant and a more or less marked ankylosis has resulted. This is not surprising when it is recalled that the pathologic changes in the cavity of the acetabulum necessitate attention, and molding of the femoral head may also be required. Lesions of the cartilage easily result which later on will cause ankylosis, and in order to avoid this it is better to clean out the joint cavity with the knife rather than with the curette, for in this way the cartilaginous covering can be better protected. Attention has also been called to the fact that after operative reduction the shortening of the limb still remains to a certain extent which may probably be attributed to some disturbance in the development of the bone.

If operative reduction is not considered proper, or if it is found impossible, resection of the femoral head may be considered. As far as I am aware, this has been done five times, and it would appear that the functional results were fairly satisfactory. It goes without saying that more or less shortening was still present after this interference and, furthermore, the shortening will increase after the patient walks. The mobility of the joint is, however, only slightly involved.

If the limb has become fixed in a functionally useless position, and particularly when it is a case of long standing, I believe that subtrochanteric osteotomy is to be strongly recommended. In cases of long standing, and in weak subjects, this operation is to be decidedly preferred to operative reduction because it is more effective than the latter and, at the same time, it is far less serious.

I am of the opinion that osteotomy is preferable to resection because it corrects the position of the limb without causing operative shortening of the femur, and it would seem particularly indicated in those cases which are seen early but where there is still an inflammatory process going on in the joint; also in all instances where the x-ray shows fixation of the femoral head resulting from exuberant overgrowth of bone; and, lastly, in elderly and weak subjects. It may also be resorted to in those unfortunate cases where, during attempts at reduction, the femur is accidently fractured, and several such instances have occurred. The few cases in which this operation has been done all show a considerable functional improvement. A slight limitation of motion and a little shortening are the only symptoms which remain.

THE TECHNIC OF ARTHROTOMY. A REPORT UPON AND DISCUSSION OF ONE HUNDRED AND NINETY-EIGHT CASES.

BY CHARLES F. PAINTER, M.D., AND ANDREW P. CORNWALL, M.D., BOSTON, MASS.

(From the Orthopedic Clinic of the Carney Hospital.)

[Continued from No. 17, p. 650.]

EXCISION.

(Female Cases.)

CASE 70. M. M., female, twenty-five. Operation, Dec. 13, 1901.

Operation not performed with tourniquet; considerable amount of blood lost during and after operation.

Cast removed on second day and large blood clot found. Stimulating measures resorted to during these two days. New cast applied. Stitches removed on sixth day. New cast applied on twelfth day. Discharged on the fifteenth day.

Aug. 22, 1902. Result perfect. No motion in joint. General condition much improved.

CASE 71. D. F., female, twenty-seven, single. Operation, Nov. 13, 1902.

Capsule found to be thoroughly infiltrated with tubercular granulations. Surfaces of both tibia and femur practically denuded. Pus evacuated from pocket in capsule above patella and a large quantity of bile-colored fluid expressed from abscess in calf of leg. Crucial ligament almost entirely destroyed. Small focus in shaft of tibia curetted out, and of necessity a thicker slice than usual removed from the apposing ends of both bones. Posterior wire and side splint used to hold leg in position.

Aug. 29, 1903. Result of excision perfect as to fixation and position. Discharge from ulcer on posterior surface of calf.

CASE 72. J. P., female, seventeen, single. Partial excision. Operation, December, 1901.

When joint was opened, capsule was found very much thickened and covered with tubercular granulations. Under surface of patella eroded. External condyle of femur except for two small bony prominences practically destroyed. Latter represented sequestra and were not the seat of active disease. Both exostoses were removed with all the surrounding synovial membrane possible. Tubercular focus curetted out of external condylar head of tibia. An abscess was opened over anterior aspect of thigh and considerable tubercular pus evacuated.

Discharged Dec. 11, 1901.

Oct. 24, 1902. Since operation, genu valgum deformity has developed. Patella is freely movable. No permanent flexion and 20° active motion present. Wearing leather leg splint.

Dec. 2, 1903. Splint worn continuously and same physical conditions present as at last visit. Instructed to omit splint one hour daily and gradually increase this period.

Oct. 22, 1906. Patient has been a nurse girl three years. No joint symptoms until recent slight injury. Condition at present does not represent an exacerbation of former condition, but a simple joint strain due to genu valgum deformity. Osteotomy advised.

Jan. 31, 1907. Deformity corrected by osteotomy eleven weeks ago. Union firm. Less motion in knee-joint. To omit plaster cast and wear flannel bandage.

CASE 73. B. M., female. Operation, Jan. 22, 1902.

Mass of broken-down caseous material found in the condyle of the femur, and capsule infiltrated throughout with tubercular granulations. Excision performed. Convalescence uneventful.

Discharged March 9, 1902, wearing plaster cast.

CASE 74. M. M., female, twenty six, single. Operation, April 14, 1902.

No evidence of active disease found. Small cavity in internal condyle of femur containing 1 oz. of fluid (cyst), probably the result of osteoporosis. About two inches of tibia and femur removed and silver wire used to approximate bony surfaces.

April 23, 1902. Cast and suture removed; under anesthetic, cast reapplied. Convalescence uneventful.

Discharged June 2, 1902. Excellent operative result.

CASE 75. E. H., female, single. Operation, July 20, 1903.

Adipose tissue found infiltrated with fibrous tissue and joint capsule much thickened. On the condylar surface of the femur the articular area was almost completely covered by a pannus. This same condition only less developed was found scattered about over all the articulating surfaces of the joint. A small cavity found near inner border of internal condyle. Ends of bones excised and patella removed.

Aug. 10. Plaster cast applied.

Sept. 1. Discharged.

CASE 76. F. P., female, twenty-three, single. Operation, Oct. 28, 1903.

Patient operated upon in Providence, R. I., six months ago and diseased bone removed from head of tibia. Incision along old scar, right knee. Bone found soft and necrotic. A large piece was lifted off with chisel and cavity beneath containing sequestrum and flocculent material. Sequestrum removed. Cavity curetted and wiped out with tincture of iodine. Connection with joint was not found. Plaster cast.

Nov. 30. Condition similar to last note. Right knee-joint opened as for excision. Synovial membrane disintegrated. Moderate excess of turbid fluid. Cartilage over condyles intact, but showed loss of luster. Cartilage over tibia presented same appearance. As a result of disease and the previous operation the internal articular cartilage was lacking, except for a narrow rim, entirely absent behind, while the internal tuberosity was the site of a large cavity nearly filled with a sub-

stance resembling large and small sago granules of glassy white luster in a scant matrix of delicate cancellated bone. This was evacuated to a depth of two inches, and head of external tuberosity being found undermined by the process, attempt to save the joint was abandoned. Articular end of femur, 2 cm., was removed, not including upper end of condyles in front or behind. Entire synovial sac removed. The patella with 0.5 cm. of extensor attached was dissected out from flap, and 1 cm. removed from head of tibia. No attempt made to remove all the new-formed substance underneath, but cavity curetted as thoroughly as possible. No hard bleeding bone was reached. Tincture iodine applied. Two wicks inserted. Posterior wire splint.

Dec. 8. Patient complained of pain in knee, and four stitches removed owing to purulent discharge.

Dec. 11. Old sinus closed with granulations.

Dec. 21. Considerable necrotic discharge. Skin not united in several places and granulations present. $AgNO_3$.

Dec. 28. Wound nearly healed. Plaster cast to leg and window cut over wound.

Jan. 10, 1904. Discharged wearing cast. Union took place between the bones, but the tumor, which proved to be a chondroma, extended further and she had a thigh amputation later on.

Case 77. G. L., female, twenty-eight, single. Operation, Sept. 15, 1905.

When joint was opened considerable tuberculous pus evacuated. A fibrous pannus was found attached to lower border of patella completely closing off lower border of patella, completely closing off lower part of joint cavity from the upper. Femoral cartilage eroded and shredded off to where infiltration of soft parts began. Cartilage over surface of tibia eroded and completely lifted off the surface of the bone. Flocculent pus found underneath and two foci in external head of tibia. Under surface of patella denuded. Excision performed.

Oct. 12, 1905. Wound completely healed. Discharged home.

Feb. 4, 1907. Some pain and swelling over outer aspect of knee ever since operation. Small discharging sinus surrounded by area of redness. Under ether a few degrees of motion are possible. Linear incision made and all possible diseased tissue removed. Tincture of iodine then applied.

Discharged two weeks later improved. No further history obtainable.

Case 78. M. E. B., female, twenty-two, single. Operation, Oct. 5, 1905.

Patient had an excision at the Massachusetts General Hospital about two years ago which has failed to unite properly. Motion in all directions can be obtained. Incision made in line of old scar. A dense fibrous pannus firmly adherent and interposed between both bony surfaces. No evidence of active disease found. Pannus removed and upper surface of tibia concaved to more advantageously hold lower end of femur when dovetailed into it. One silver wire suture used to hold external bony surfaces in apposition. Several silk sutures used on inside for same purpose.

Oct. 31. Discharged wearing plaster.

Dec. 27, 1905. Less mobility of joint than before operation.

Feb. 5, 1906. Pathological report from tissue removed — active tuberculosis. Joint fairly rigid. Continue plaster.

April 28. No lateral mobility. Slight flexion. Five centimeters shortening.

Sept. 6. Plaster removed. Flannel bandage with felt reinforcements.

Sept. 18, 1907. Able to walk any distance without pain. Bones solidly united. In good position. Requires no apparatus.

Case 79. A. B., female, twenty-eight. Operation, Feb. 23, 1906.

When joint was opened, patella was found bound down with adhesions. Many erosions and fibrous adhesions were found throughout entire joint. As the condition represents an old infectious arthritis, less of the trochlear surfaces were removed than in the excision of tubercular joint disease.

Convalescence uneventful as to knee. Transferred to Surgical Service for appendectomy in April, and finally discharged June 15, 1908.

No further history obtainable.

Case 80. L. T., female, twenty, single. Operation, Jan. 30, 1907. This was a case of infectious polyarthritis. Sepsis came from within, the operation having fanned an old infectious process into existence.

Patella adherent, cartilage everywhere eroded. Bone very soft and friable. Small wedge-shaped piece removed from mid-anterior lower end of femur to allow cavity for patella. Excision otherwise not of special interest.

Two days later wound found septic. This intervention terminated fatally March 16, 1907.

Autopsy: Knee-joint found bathed with semifluid, brown, purulent exudate. Section of soft tissues closely adjacent show several small foci (abscess) containing creamy-yellow pus. Both femoral artery and vein normal.

Anatomical diagnosis: Operative wound with extensive localized suppuration. Decubitus over base of sacrum and heels. Pressure ulcer on right leg, and question of toxemia. Blood culture negative. Culture from knee-joint, streptococcus pyogenes and bacillus coli communis.

Case 81. C. B., female, sixteen, single. Operation, March 29, 1907.

Operation performed and ½ inch of tibia and femur removed to correct or improve old infantile knee. Arthrodesis of ankle.

Discharged April 25, wearing plaster cast to groin.

Aug. 16, 1907. New plaster cast applied. Position good.

Sept. 16, 1907. Cast removed at home without instructions. Motion in all directions at knee. Flexion and extension at ankle-joint. Operation was refused and patient continued wearing plaster cast to Sept. 28, 1909, when she re-entered the hospital and an excision of the knee was performed on the following day.

Bone typical of infantile paralytic disease. Fibrous pannus over both bony surfaces, which was removed, together with thin slice of bone.

Convalescence uneventful.

Dec. 18, 1909. Excellent result. Firm bony union at knee-joint. Plaster cast removed and reapplied.

Case 82. E. R. D., female, fifty-four, married. Operation, May 3, 1907.

Linear incision over outer side of right knee, but joint not opened. Tissue, infiltrated with and containing area of cheesy, degenerated material, size of pigeon's egg, removed. Joint opened on inner side and large part of articular cartilage found destroyed. Small portion of semilunar cartilage which was free in the joint cavity and portion of the articular cartilage removed for pathological examination. Patient discharged. May 16, 1907, wearing plaster cast.

Re-entered hospital Jan. 23, 1909. Several discharging sinuses have developed during interim. Knee is held in 15° flexion. Complains of pain, swelling and limitation of motion.

Excision performed. Throughout knee-joint destruction had taken place. Few remaining portions of

cartilage were found and much eroded bone containing small foci representing an active process. Some areas of healed tubercular granulation tissue found. Considerable blood lost during the operation. Leg put up on posterior wire splint and plaster cast was applied three days later with windows over both lateral aspects of knee-joint.

Discharged March 11, 1909. Wound healed except for two discharging sinuses.

Jan. 1, 1910. Patient has a fair functional result and is able to get about the house. No pain or tenderness for past few months. Sinuses still discharge. Should have had an amputation, but refuses it now.

CASE 83. N. B., female, twenty, single. Operation, Oct. 13, 1909.

Patient has had several discharging sinuses about right knee for a long period of time. When joint was opened some free tuberculous pus and marked destruction of the joint was found. Many small foci (bone) were present, necessitating the removal of a thick slice of bone from both tibia and femur. Patella and entire quadriceps pouch removed.

Convalescence uneventful.

Plaster changed Oct. 27, 1909, and patient was discharged to Out-Patient Department.

Dec. 13, 1909. No symptoms. Plaster removed and new one applied.

Among the series of 30 excisions was one case of chondroma; three of infantile paralysis and two of infectious arthritis; one of these was a polyarthritis.

There was one death attributable directly to the operation, that being in the case of infectious polyarthritis.

There were three infected joints, but no serious consequences resulted. Convalescence was not even retarded by it in any case. There was one other case that had a stitch abscess. Twenty-four of the excisions were for tuberculosis. Two of these died some months after the operation, one from miliary tuberculosis and one from phthisis. One of the cases had a partial excision, one femoral and the corresponding tibial condyle. She secured a good degree of motion in the joint, and after having an osteotomy to correct her knock-knee, she had a very serviceable articulation. Two cases already referred to had secondary excisions. Only one was lost sight of before union was complete. Only one did not have satisfactory position. Three only of these cases had metal sutures used. Two of these had them removed, and in one there was slight necrosis about the stitch. One still has the wire in place. Twelve were females and 18 were males.

The important technical matters to observe in performing excisions of the knee are to remove the osseous disease wholly along the cut surfaces and to be sure of an accurate approximation of the cut surfaces. If these two rules are observed the necessity for metal sutures or plates of any kind will rarely if ever occur.

A small series of erasions follow. Most of these were performed for tuberculous disease. The technic of getting at the interior of the joint is not in any way dissimilar from the technic used in the excision operations. The operation is not, in our opinion, to be compared in its beneficial effects with the operation of excision. Whether it be accomplished by sawing through the patella and flexing the knee, or by dividing the patellar tendon and reflecting back the patella, thus exposing the quadriceps pouch, the convalescence is protracted to such an extent by the union of the bone or the tendon (whichever method is employed) that there is very little likelihood of obtaining enough motion to justify the operation in such an articulation as the knee. In other joints it might be used in selected cases, but seldom in the knee. The difficulty is not in securing a pathological cure, but in procuring enough function to justify the operation. One of the things that has been brought out from a study of these cases and the excisions is that tuberculosis in the knee at any rate starts very much more frequently than has generally been supposed from the synovial membrane, and is likely to invade the cartilage and bones if a tuberculous synovial pannus be allowed to lie too long in contact with such structures. In certain selected cases an erasion and the procurement of a pathological cure, even though very little motion should be secured, might be subjected later to an arthroplasty to secure motion. Several of these cases have had 20° of motion for a year or so after the operation, but have gradually lost it and have been a great deal better off when ankylosis had taken place. The recent observations of Ely upon the pathology of tuberculous joints are interesting and offer further support to the contention here made that erasion is not as good an operation as excision in a majority of tuberculous involvements of the knee-joint. Some surgeons are employing arthroplasty after the method of Murphy in these tuberculous cases, but the results are, in our opinion, not sufficiently satisfactory to justify its employment. The transplantation of an entire joint may in the future yield better results.

ERASION.

CASE 84. J. J., male, seventeen, single. Operation, Aug. 23, 1901.

Right knee opened as for excision of the joint. After the thickened synovial membrane was throughly dissected away, a necrotic area, apparently the original focus of disease, was found in the external condyle of the femur. This was thoroughly curetted; also a few eroded areas of cartilage found over articular surfaces of both bones, and the joint was irrigated with sterile water. Patellar tendon restored with silk sutures and wound closed. Plaster cast applied.

Sept. 19. Discharged. No symptoms to note.

Jan. 15, 1902. Few degrees of motion in joint. No symptoms.

March 31. Few degrees of motion persist. Patient wearing leather cast. Patient moved to Canada and he reports by letter that he has a useful limb but no motion.

CASE 85. P. L., male. Operation, Aug. 4, 1902.

Right knee opened on inner side. Capsule thick and hypervascular. Incision continued as for excision of the joint. Synovial membrane .5 to .8 cm. in thickness, and glossy, resembling a tubercular condition. Both condyles of femur covered over outer side by a pannus closely adherent to cartilage which rendered it striated and almost eroded. A communicating bursa in the popliteal space contained tubercular pus, fibrin flakes

and caseous fragments. The synovial membrane was completely removed and no bony invasion could be found. A counter-opening made to drain popliteal space. Tincture of iodine applied and joint irrigated with corrosive solution. Wound closed leaving wick. Posterior wire splint.

Aug. 18. Plaster cast applied. Slight discharge from posterior drain.

Aug. 25. Wound dressed through window in cast. Slight discharge persists. General condition improved. Discharged.

Sept. 30, 1902. Sinus has nearly healed. Patient to continue use of cast. No further history can be obtained.

Case 86. B. McQ., male, twenty, single. Operation, Aug. 18, 1905.

Right knee-joint opened as if excision were to be performed. Considerable tubercular granulation tissue about internal condyle and a fibrous pannus covered most of the external condyle. Cartilage over internal condyle was elevated from the surface of the bone, but disease underneath was very superficial and apparently represented the ingrowth of granulation tissue rather than any active disease. The whole general appearance of the upper surface of the joint indicated that the disease was well spent. Synovial membrane where it showed disease was removed. Pannus and eroded cartilage also excised. Tincture of iodine applied and joint irrigated with sterile water. Deformity left undisturbed, preferring to do a Macewen osteotomy later if disease is entirely extirpated, as an excision would have shortened the leg too much and there seemed a fair chance that the active process could be completely removed. Wound closed and cast applied.

Sept. 5, 1905. Discharged wearing new cast.

Case 87. J. F. M., male, twenty-six, married. Operation, Oct. 24 (?), 1905.

Right knee-joint opened as for excision. The small amount of the synovial membrane found diseased was removed. Necrotic bone was found over the surface of the tibia and femur and was removed with curette as far as possible. Joint capsule united and plaster cast applied.

Nov. 2. New cast applied.

Nov. 7. Discharged. No pain or tenderness.

February, 1906. X-ray shows process extending downward from tibial head. An excision was attempted, but both bones were found badly diseased and an amputation seemed advisable. This was accordingly done, the patient having been previously prepared for this outcome.

March 25, 1906. Wound entirely healed. No symptoms.

Case 88. C. L. R., male, forty-three. Operation, Aug. 10, 1906.

Incision as for excision of left knee. A pannus of dark fibrous tissue removed from internal condyle. Synovia throughout joint thickened. X-ray showed focus in internal condyle, but trephining did not verify this interpretation. A small focus of diseased bone found over external condyle removed. Ninety-five per cent carbolic applied and immediately followed by alcohol. All diseased tissue removed and tincture of iodine applied. Wound closed and leg put up in posterior wire splint.

Convalescence was delayed owing to collection of serum and ooze from wound.

Aug. 24. Plaster cast applied.

Sept. 11. Discharged home.

Case 89. W. R. M., male. Operation, March 14, 1908.

When left knee was opened a large fibrinous clot was removed. Cartilage was thick and eroded under pannus, which covered both femoral condyles and dipped down between to some extent. Pannus and diseased capsule removed as far as possible. Patella normal. A portion of one semilunar cartilage was found partially detached and was removed. Adhesions in the quadriceps pouch broken up and considerable fibrinous material removed. Tincture of iodine applied and joint closed, leaving drain in either inferior angle of wound. Long posterior wire splint applied.

March 29. Plaster cast including foot.

April 2. Patient has apparently an incipient tubercular meningitis.

April 4. Discharged against advice. Died four days later.

Case 90. L. N., male, nineteen, single. Erasion of left knee. Operation, Dec. 29, 1908.

Left knee opened as for excision. Leg flexed after joint was opened. No erosion of joint surface, but large pannus, purple in color, over trochlear surface of femoral condyle, covering outer ¼ inch of cartilaginous margin. No adhesions present in quadriceps, but entire surface covered with pannus of same nature as that found over condyle, somewhat thicker, however. Over outer border and attached at margin of external condyle was a fungus-like mass, size of English walnut, connected to bone by a fibrous pedicle below border of cartilage, which, however, did not seem to lead down to any osseous focus. Capsule not thickened below quadratus bursa. Patella normal. Pannus removed as far as possible and fungus mass excised. Tincture of iodine applied. Joint surface restored. Two iodized wicks left in infra-patellar space. Plaster cast applied.

Jan. 11. New cast applied.

Jan. 19. Discharged home.

Case 91. D. L., male, thirty-three, single. Operation, March 21, 1909.

Left knee-joint opened over inner side. Many floccular masses found in the joint. Few fringes of a similar nature found, especially over inner condyle of femur, and removed. Tincture of iodine applied. Wound closed and light plaster cast applied.

May 28. About 10° motion in knee.

July 16. Patient's knee in good condition. Has no pain or discomfort. Apparently progressing favorably. To be allowed more motion. To wear split cast a half day only.

July 23. To leave off cast entirely.

Aug. 6. No surface heat. Patella movable. Some thickening in quadriceps pouch. Knee brace allowing only 10° motion.

Case 92. J. G. D., male, twenty-three, single. Operation May 5, 1909.

Left knee-joint opened through linear incision over inner aspect. Numerous soft brown villi, in size and appearance like earth-worm, and a small quantity of brownish fluid, found and removed. Small fatty mass excised from under surface of patella. A hard, smooth body attached by pedicle was found in the quadriceps pouch and removed with some difficulty. Joint irrigated with salt solution and wound closed.

May 26. Motion to a right angle. Pathological report: Tuberculosis of soft parts. Knee swollen. Plaster cast applied.

June 15. Discharged, wearing split cast.

Case 93. M. D., female, twenty-eight, single. Operation, Nov. 11, 1904.

Incision 4 cm. long made over and parallel with the middle metacarpophalangeal joint of the right hand. Blunt dissection and retraction of the tendons exposed the joint. Capsule not well-defined, but was thickened by granulation tissue adherent to the bone.

In the joint was found necrotic granulation tissue. Base of phalanx removed owing to its necrotic condition.

A small specimen of bone was removed from the metacarpal bone for pathological purposes. Tincture of iodine applied and wound closed.

Nov. 16, 1904. Discharged. Small granulating area at center of wound.

(To be continued.)

Clinical Department.

STOMACH DISEASES FROM A MEDICAL STANDPOINT.

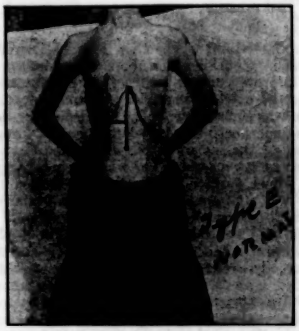
BY GEORGE ALBERT McEVOY, M.D., BOSTON.

MEDICALLY these diseases cover too large a field to be lightly passed over, and in conversation with recent graduates I have learned that sufficient attention has not been paid to this subject, and because of this it is quite easy to understand why the surgeons are claiming, and rightfully, the cure of digestive disturbances by surgical procedure.

After some experience in the treatment of these diseases, and with all fairness to the profession, many things have been impressed upon me, the most noticeable being the apparent lack of knowledge or total disregard of the use of the stomach tube, which, when used, is mostly for the purpose of lavage instead of for its real value, i. e., as a means of diagnosis.

The following cases stated briefly will demonstrate quite conclusively the absolute need of the tube.

No. 1. Thomas S., forty-six, mill-man, pain over epigastrium for one year, considerable gas, loss in weight 25 lb. Test by tube showed normal secretions and the physical examination was negative. Diagnosis: Nervous dyspepsia, and under treatment complete recovery. A previous diagnosis of cancer had been made.



No. 2. Ellen M., twenty-six, single, maid, sudden pain over whole of abdomen with considerable vomiting. Test by tube showed an excessive free HCl acid and the physical examination showed tenderness over abdomen, most marked over epigastrium. Hyperchlorhydria the diagnosis. Under treatment rapid recovery. A previous diagnosis of appendicitis had been made and operation advised.

No. 3. M. F., thirty-three, student, pain in epigastrium for fourteen months, increasing in severity until it caused vomiting; consulted many physicians, some of whom advised operation for gallstones. Test by tube showed an excessive free HCl, and under treatment made a rapid recovery. Diagnosis, ulcer.

It is quite evident that these few cases demonstrate the real value of the tube, and it has seemed strange to me that physicians should cast aside this means of obtaining proofs which are just as positive and easily obtained as are those in lung, kidney and throat cases. Is it that the methods for obtaining such proofs are considered by the profession too difficult and disagreeable, or is it because the necessity for such proofs is inadequately taught?

Having shown the value of the tube in determining the first proof in the treatment, the next step of importance to consider is the position of the stomach with reference to its size and motility. The simplest and probably the most convenient method for general use is the CO_2 for demonstrating the position and size, and a test dinner or supper to determine its motility.

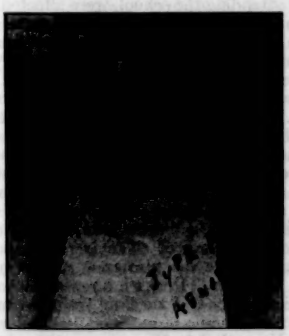
In reference to the position, size and motility, we can learn a great deal that will help us in our treatment by considering the construction of the body with reference to the stomach. In relation to this consideration we have two different types of body; i. e., habitus enteropticus, and habitus

Type E, normal.

Type A, normal.

apoplecticus. The habitus enteropticus type is represented by a line drawn from the end of the xiphoid to the umbilicus, one half of which is much greater than that of a line drawn from the center of this line to meet one drawn vertically from the middle of the clavicle. The habitus apoplecticus type is represented by a line drawn from the end of the xiphoid to the umbilicus, one half of which is equal to or shorter than that of a line drawn from the center of this line to one drawn vertically from the middle of the clavicle.

We are taught in physics that the gravity of a



body moves in the plane of least resistance, and, applying this fact in our demonstration, it is easy to understand why in habitus enteropticus type the course of the stomach is downward, while in habitus apoplecticus it is toward the right.

The importance of considering these types as an aid in our treatment is shown by considering the results which are produced pathologically. In habitus enteropticus invariably the end result

Type E, abnormal.

is a gastroptosis with dilatation due to the prolapse and motor insufficiency, while in habitus apoplecticus the result is quite different, because

Type A, abnormal.

any change in position and size is usually at the expense of the lower border, which is generally forced downward and to the right, while invariably the upper border remains normal.

A brief explanation of how the changes are produced will further simplify our understanding in the treatment of these types of body. We know that in the habitus enteropticus type the tendency of the stomach is downward, and, because of its attachment to the duodenum, which is never more than slightly movable, we shall sooner or later, if the prolapse continues, have a kinking or constriction at or about the pylorus which shall, if too much work is thrown upon the stomach, cause a motor insufficiency producing a dilatation, while in the habitus apoplecticus type most all of the conditions begin with an increase of the acid secretions and, as a result of this increase, we can have dilatation produced in different ways, as by spasm of the pylorus or by a narrowing of the pyloric orifice by healing of an ulcer.

It can be seen from these few facts that the end result in both types, if the cause is continued long enough, is a dilatation, and as its production is different, so also must be the treatment, and as the subject of treatment is too important and extensive to be discussed in this paper, I shall only mention the principle of the treatment in relation to the conditions found. For instance: In a case of gastroptosis with motor insufficiency producing a dilatation, the principle of the treatment is to consider how much the stomach has prolapsed and how extensive is the dilatation because of the motor insufficiency, and then arises the question as to quality, quantity and the intervals of administering the treatment, and from this instance, as in many others, the problem of treatment is to treat the cause. But if the cause has left its results, we must treat the results, for in many cases, while we cannot remove the cause, we are able to correct the results.

Conclusion: It is quite evident after what I have shown that if we pay special attention to the proper use of the tube as a diagnostic measure, and treat the diseases according to the mechanical changes produced pathologically, better results will be obtained medically and fewer cases be referred to the surgeons.

Medical Progress.

REPORT ON NEUROLOGY.

BY PHILIP COOMBS KNAPP, A.M., M.D.

POLIOMYELITIS.

Wickman [1] has recently reported the results of a pathological study of seven cases of poliomyelitis occurring in the great Swedish epidemic of 1905 of over one thousand cases, described in his well-known work. These cases all died in the acute stage of the disease, in from two and a half to eight days after the onset, and most of them showed an ascending paralysis, as in Landry's disease. In all cases there was infiltration of the spinal pia, especially in the lumbar region, with occasional patches of infiltration in the cerebral pia. One of the most striking changes was the accumulation of round cells about the blood vessels and elsewhere, especially in the anterior horns, but also in the posterior horns. There were occasional small hemorrhages in the gray matter of the cord, and sometimes in the white matter. Edema in portions of the cord was very common. In no case was there any indication of thrombosis or embolism. The accumulation of round cells in

the neighborhood of the ganglion cells is the cause of the rapid destruction and disappearance of the ganglion cells by neuronophagy. Vascular and interstitial changes are also constant in the medulla and brain stem, most pronounced in the reticular substance, but occurring elsewhere without showing a special predilection for the motor nuclei. Similar changes were found in various parts of the brain, the cortex, the basal ganglia and the cerebellum. He regards poliomyelitis as an acute, infiltrative, non-purulent inflammation of the lymphocytic type. In the very earliest period there is a migration of the polynuclear leucocytes. Polyblasts also develop and play the chief part in the process of infiltration. The greater extent of the process in the anterior horns is due to the fact that they are more vascular than any other part of the cord.

Hoffmann [3] has reported the case of a young man of twenty, who had previously been deaf and partly blind, and who developed pain in the wrist and a heavy feeling in the back. A few days later he had a sudden tremor in the arms, and during the night the right arm became completely paralyzed (upper arm type), and the left leg partly paralyzed. The paralysis was flaccid and atrophic with reaction of degeneration. He had Hutchinson's triad of signs of hereditary syphilis, and the cerebrospinal fluid showed increased lymphocytosis, albumen, inhibition of hemolysis and agglutination of erythrocytes. The clinical picture, except for the examination of the cerebrospinal fluid, was typical of acute poliomyelitis. Under syphilitic treatment the leg recovered and the arm improved. Preobraschenski [3] has reported a somewhat similar case in a man of forty-six, who had had syphilis fifteen years before. For two days the limb had felt weak, the weakness increasing rapidly until both arms and one leg were paralyzed. On the fourth day there was complete paralysis of all four limbs. In about two months he died, with signs of respiratory paralysis. There was an extensive poliomyelitis of both anterior horns from the mid-cervical region down, the blood vessels were increased, their walls thickened, the membranes were thickened and adherent, and there was a pronounced cellular infiltration — a true syphilitic poliomyelitis. These syphilitic cases are extremely rare, but it is most important to recognize that they do occur, and to investigate the possibility of a syphilitic origin in dealing with any case of poliomyelitis.

Batten [4] reports two cases which raise an interesting question. A child of two years had had weakness of the left arm from birth, but weakness of the legs was not noticed until between the age of one and two years. The left upper arm was much wasted, the legs were also wasted, the right more than the left, and they were blue and cold. The legs were very weak, but the child could bear his weight on the left. There were diminished reflexes and reaction of degeneration. The legs improved so that he could walk, but the arm was helpless. Six years later he died of diphtheria. There was a marked diminution of cells in the left anterior horn in the fifth cervical segment, and in both anterior horns in the lowest dorsal, third lumbar and second sacral segments (which were selected for microscopical examination), with diminution in the size of the cord and areas where medullated fibers were absent, the changes being similar to those found in late cases of poliomyelitis. A second case, said to be congenital, showed a typical atrophic paralysis of the right leg, and poliomyelitic changes in the cord. After a careful consideration of various theories, Batten believes that the first case was very probably, and the second possibly, intrauterine poliomyelitis.

Experience in this country in the last three years has been such as to make previous records of epidemics, even in Sweden, almost insignificant, yet there have been a good many epidemics reported which, in the past, would have been regarded as severe. Lindner and Mally [5] report an epidemic in September, 1908, in the vicinity of Grossraming, in upper Austria. Between September, 1908, and February, 1909, 94 cases occurred, 16 of which were fatal; 37 occurred in children under three, 4 in adults over twenty; 37 were females, 57 males. The origin of the epidemic could not be traced to any other epidemics, and the theory was advanced that it might have arisen from some sporadic case. The clinical picture showed many variations from the classical type, and abortive cases occurred. The disease affected persons dwelling in the same house, and there was proof of direct contact or indirect contact through a third person. Children living far apart, but attending the same school or having others in the family attending the school, were affected. There was no evidence of transmission by water or food. All the ascertainable facts favored the transmission from one person to another. Hoffmann [6] reports 36 cases occurring near Heidelberg from June to October, 1908, 20 below the age of two, and 2 adults. There was no increase in acute encephalitis with spastic hemiplegia or in polyneuritis in that time. Zappert [7] reports 266 cases occurring in lower Austria in the summer and autumn of 1908. Krause [8] studied over 100 cases in an epidemic at Hagen in the summer of 1909. Ninety per cent of these began with gastro-intestinal symptoms. Many of them were nurslings. In one region there was also great mortality among young chickens. Recksch [9] reports 93 cases in the neighborhood of Bochum from the middle of July to the middle of October, 1909, of whom 17 died. Neurath,[10] in Vienna, saw 3 cases in 1902, 45 in 1908 and 28 in the first half of 1909. Other data not yet fully formulated indicate that the epidemic in 1908 and 1909 has been pretty extensive throughout Germany and Austria. The French and Italian journals, however, do not show any special epidemics in those countries. Treves [11] has collected the record of thirty-two epidemics, thirteen of which occurred in Sweden, and only two small ones, seven cases in all, in England, although many cases which were never collected occurred in London within the last few years. He reports an epidemic of eight cases in the village of Upminster, with a population of 1,477, between

July and September, 1908. The origin could not be traced. Stephens [13] reports 135 cases occurring in Victoria, Australia, in the first half of 1908, chiefly in the autumn months, April to June, with a death-rate of 4.5%. Most of the cases occurred in Melbourne and seemed mildly contagious. There was a considerable epidemic in Queensland in 1905. Although the occasional epidemic occurrence of poliomyelitis has been recognized since 1881, the remarkable increase in the last five years is as yet unexplained. The disease has been recognized for so long a time, and is ordinarily so easy of recognition, that the increase cannot be imputed to an increase in our diagnostic skill. Whether the great Swedish epidemic of 1905 and the epidemic in Queensland in the same year can be regarded as in any way the sources of the subsequent epidemics in America, Germany and Australia, is a problem.

SYPHILIS OF THE NERVOUS SYSTEM.

Mott [13] classifies syphilitic diseases of the nervous system as follows: (1) *a*. Syphilitic diseases of the brain, comprising basilar meningitis, meningitis of the convexity, cerebrospinal meningitis, arteritis and gummatous tumors. All these conditions may be more or less combined in the severe and early forms of the disease. *b*. Syphilitic diseases of the spinal cord. (2) Parasyphilitic affections: tabes dorsalis, tabes optica, paralytic dementia. The whole cerebrospinal axis is usually, if not always, affected, although the chief symptoms may be cerebral or spinal. He contends that a slight meningitis may often be associated with the early stages of syphilis, as is shown not only by such clinical symptoms as ocular troubles and paralysis of cranial nerves, but by the frequent existence of lymphocytosis during this period. In parasyphilitic and syphilitic meningitic affections the lymphocytes in the cerebrospinal fluid are greatly increased in numbers. In syphilitic cases the lymphocytes diminish under antisyphilitic treatment, and as the symptoms diminish, but in parasyphilitic disease they do not. Lymphocytosis, however, may occur with other diseases. In general paralysis, and, to a less degree, in tabes, there is an increase in proteid in the cerebrospinal fluid. The Wassermann test of the cerebrospinal fluid proved positive in 59 out of 64 cases of paresis (92.1%), but in 63 cases not suffering from paresis it was not once found to be positive. In cases of atypical tabes and paresis where the Wassermann reaction is not obtained when the cerebrospinal fluid is examined, and the lymphocyte reaction is marked, antisyphilitic treatment should be instituted. Clinical indications of pseudo-tabes are sudden onset and rapid progress of symptoms, early appearance after primary infection, variability of the reflexes, central scotoma in one eye, and marked improvement under treatment. Why only about 3½ per cent of those infected with syphilis subsequently suffer from the parasyphilitic affections is still an unsolved problem. Parasyphilitic affections are more apt to follow mild or even unrecognized syphilis. The virus may be modified, acquiring a special neurotoxic action, as is shown by the fact that sometimes a large percentage of parasyphilitic affections follow infection from a single source, of which Mott cites many interesting examples. This speculation is somewhat contra-indicated by experiments on animals, so that it seems more probable that the variation of effects is due, not to a variation of the virus, but to the reaction of the individual. All conditions which tend to active metabolism of systems of neurones will, in conjunction with the stimulating effect of the syphilitic poison, cause the nerve cells to exercise an abnormal metabolic activity in the production of the side-chain molecules necessary for immunization, thus leading to decay.

Nonne and Holzmann [14] report investigations on 49 cases of tabes, 20 cases of paresis, 22 cases of cerebral and spinal syphilis, 12 cases of multiple sclerosis, 33 cases of epilepsy, 6 cases of neurasthenia, 3 of which had had syphilis, 10 cases of alcoholic pseudotabes, and 17 cases of cerebral tumor. In tabes and paresis, lymphocytosis and the globuline reaction (Phase I) are almost always present. Both reactions are very rarely absent in cerebrospinal syphilis. In multiple sclerosis they occur in a minority of the cases and are weak. In epilepsy, neurasthenia, pseudotabes and tumor they are absent, unless there be syphilis, when there may be a feeble lymphocytosis, but Phase I almost always is absent. The Wassermann reaction occurs in the blood serum in 60 to 70% of the cases of tabes, but is almost always negative in the cerebrospinal fluid. In paresis, on the contrary, it is almost always positive both in the serum and in the cerebrospinal fluid, and seems an important factor in the differential diagnosis. It may be negative in the cerebrospinal fluid in hereditary paresis. In epilepsy and brain tumor the Wassermann reaction is negative unless there be syphilis, when it may be positive in the blood serum. All four reactions are independent of the stage and the special variety in the course of syphilis. In a further study [15] of 93 cases of tabes they confirm the statement that the Wassermann reaction, conducted by the original method, is negative in the cerebrospinal fluid in simple tabes, which is a help in the differential diagnosis from incipient paresis with involvement of the posterior columns and from tabes with beginning paresis. In a later study Nonne [16] presents the data derived from 40 cases of paresis, 104 cases of tabes, 29 cases of cerebrospinal syphilis, 17 cases of multiple sclerosis, 14 cases of brain tumor and 37 cases of epilepsy, 394 in all. These investigations practically confirm his previous conclusions; lymphocytosis, however, is not always alike in different examinations of the same patient, and that and Phase I may exceptionally be absent in tabes, paresis and cerebrospinal syphilis. The Wassermann reaction is sometimes positive in the serum in scarlet fever. It is important to distinguish between the reaction in the serum and in the cerebrospinal fluid. In rare cases it is negative in the serum in paresis, but it may be positive on subsequent examination; if, on repeated examinations, it be negative in the serum, we must

look with suspicion on the diagnosis of paresis. The same is true of the reaction in the cerebrospinal fluid. In paresis all four reactions (lymphocytosis, Phase I, Wassermann serum and Wassermann fluid) are positive. In tabes, lymphocytosis and Phase I positive; Wassermann serum positive in 60%; Wassermann fluid negative. In cerebrospinal syphilis, lymphocytosis and Phase I positive, Wassermann serum more often positive than in tabes, Wassermann fluid negative. In multiple sclerosis, lymphocytosis and Phase I may occur, but are weak; Wassermann serum may exceptionally be positive; Wassermann fluid negative. In tumor, lymphocytosis and Phase I may occur, but are weak; both Wassermann tests are negative. In epilepsy, all four are negative.

On the clinical side Nonne [17] cites various cases to prove what is now well recognized, that syphilis may attack the nervous system in the early period of the disease, two to four months after the initial lesion. After the tenth year cerebral syphilis is rare, but cases have been known thirty and even forty years after infection. When syphilis is acquired late in life it seems more liable to affect the nervous system and to run a more severe course. He is more disposed than Mott to explain the occurrence of parasyphilitic affections by assuming that there is a special neurotoxine in the infecting virus. Mott and Nonne both agree that syphilis is more apt to attack the nervous system if mercurial treatment has been insufficient or has been wholly omitted. Mott believes that if the spirochete has once gained access to the subarachnoid space it is very difficult to dislodge, so that, if this takes place early, the most thorough mercurial treatment may be of little avail.

A word must be added in regard to Ehrlich and Hata's new treatment of syphilis by dioxid-amido-arseno-benzol, or "606," concerning which Simonelli [18] has just published an excellent critical digest of the various articles. Ehrlich's aim has been to find some substance which would have a special chemical affinity for the spirochete, without harming the general organism. This he has used in one single dose — *therapia magna sterilisans*. After trial of many substances he has found "606" the most efficacious. The best method at present of administering the drug seems to be that endovenous injection as practised by Hoppe and Schreiber,[19] which causes less pain than the intramuscular injection, and is not followed by the local reaction. The injection is sometimes followed by a considerable rise of temperature, some cardiac irregularity and skin eruptions. In the few cases where serious consequences have followed, they have been due to some co-existing disorder. In the great majority of reported cases the new remedy seems to have given remarkably good results, both in the primary, secondary and tertiary stages of syphilis, and in a very considerable percentage of cases the Wassermann reaction has changed from positive to negative. Wechselmann,[20] Neisser,[21] Treupel [22] and Glück [23] report cures or marked amelioration in a number of cases of severe cerebral syphilis, but Glück had found no benefit in the treatment of three cases of parasyphilitic affection, two of paresis and one of optic atrophy. Up to the present time it seems doubtful whether there have been any true relapses after the treatment, but it is too early to decide whether it does actually cut short the disease.

Reports of Societies.

THE AMERICAN CLIMATOLOGICAL ASSOCIATION.

WASHINGTON, D. C., MAY 3, 4 AND 5, 1910.

THE twenty-seventh annual meeting of the American Climatological Association was called to order by the President, DR. EDWARD R. BALDWIN, of Saranac Lake, N. Y., at the Willard Hotel, Washington, D. C., May 3, 1910, at 10 A.M. The secretary called the roll and seventy-five members were found to be present or attended the later sessions.

Dr. Baldwin then gave the President's Address on

THE ORGANIZATION OF HEALTH RESORTS.

He stated that, owing to the rapid change in the attitude of the public in reference to fear of contagion in tuberculosis, there is a new problem presented in health resorts.

Sanatoria and hospital care are increasing, but the patient's sojourn in them is temporary. Colonization of the tuberculous in the vicinity of sanatoria, as well as in western and southwestern resorts, continues, but the patients are increasingly from the chronic or arrested class who have tried home or institutional treatment.

Result: Sooner or later more dependents and representing a class who have obtained a legal residence in the community. They should be better cared for than in the average county hospital. There should be some system of co-operation with local and other charitable agencies by means of a central bureau of information, whose secretaries shall seek out the patients requiring aid, refer them to proper authorities, or secure aid from their former homes. Reception hospitals needed from which they may be sent to sanatoria or back to former homes.

DR. ALBERT C. GETCHELL read a paper on the

SUMMER CLIMATE OF MAINE,

in which he took up the following points:

Has the Maine summer climate power to restore the sick as it evidently has to refresh the tired?

Geographical considerations: Latitude, mountain, lake, forest, seacoast. Climate: Varieties of weather, temperature, sunshine, soil. Facilities of transportation. Living accommodations in hotels, boarding

houses and camps. Personal experiences with persons who have been benefited by a summer sojourn in Maine for respiratory troubles.

Dr. Getchell said the chief charm of Maine is its water, seashore, lakes and ponds. He described Sebago Lake, the Rangeleys and Moosehead Lake, the Belgrade Ponds and the opportunities for sport of all kinds. The climate is changeable and these changes are of greater intensity in winter than in summer. The periods of heat are short, and even then the heat is tempered by the large extent of forests, lakes, rivers and ocean. The trend of the coast is such that the hot winds of summer from the south and southwest come over the ocean so that hot days are rare compared with other parts of the New England coast. Owing to the deep bays and inlets of nearly the entire length of the coast, one has an opportunity to select his ocean climate from that of the outlying islands and headlands, where one is practically out at sea and the weather is cool, even cold, to the inland and sheltered nooks, where one gets the heat of the land with the diurnal, tempered and refreshing sea breeze. Dr. Getchell referred to the fogs and the sunshine and made some comparisons between the clear, partly cloudy and cloudy days in Maine and Colorado during June, July, August and September. The comparison was quite favorable. The influx of summer visitors was referred to. Large numbers go in the autumn for deer and moose hunting. Dr. Getchell cited cases of tuberculosis which improved greatly in Maine during the summer near Belfast and Rockland. Another patient recovered health in the Aroostook country. Dr. Getchell spoke very favorably of the neighborhood of the Katahdin Iron Works, about thirty miles east of the southern end of Moosehead Lake. There are areas in Maine, near the Rangeley Lakes, in which relief has been found for hay fever in Dr. Getchell's experience. The ocean climate of Isle au Haut is suitable for the hay fever sufferer. So, also, in places on Mount Desert Island. The coast is a restorer of tired and worn-out bodies, but the summer of the Maine coast is cool and a certain type of delicate person, not to say invalid, finds it difficult to keep sufficiently warm to be comfortable. Dr. Getchell referred to the Maine Sanatorium for Tubercular Patients at Hebron, and also to the famous Poland Springs.

DISCUSSION.

Dr. E. O. Otis, of Boston, Mass.: In this connection it may be well to mention the adjacent coast region of New Hampshire. This short coast line, thirteen miles in extent from the Piscataqua to the Merrimac, for the larger part is composed of sandy beaches, in contrast with the rocky character of the Maine shores. From personal experience of several years with the summer climate of both the Maine and the New Hampshire coasts, it has appeared to me that on the latter coast there is a little drier atmosphere. In other respects, so far as the temperature and the climate are concerned, the conditions of the southern Maine and New Hampshire coasts seem very similar.

Dr. C. L. Minor, Asheville, N. C.: I have had a personal opportunity of noting the value of the Maine summer climate in pulmonary trouble. I have not tried the up country of which Dr. Getchell speaks, but have tried the coast, and, despite the fogs, have found the latter admirable. There is not only a very cool summer, which is important, but there is a combination of the brace of mountain air with the tang of the sea air which has a wonderfully stimulating and appetizing effect, and I believe, in properly selected cases, with slight trouble and moderate symptoms, that the Maine coast in the summer is to be thoroughly recommended, and that you would have to go into Upper Canada to get as good.

Dr. Guy Hinsdale, of Hot Springs, Va.: I would like to say a word about the climate of the coast of Maine. I have had some experience with it for the last twelve or thirteen years, and I read a paper before this Association on the climate of Maine in 1901. The soil of the coast is more sandy than that of the interior, and the air of the coast is not so damp as most people think. I agree with Dr. Bowditch in his views regarding the dryness of fogs of Maine. It seems paradoxical to speak of dry fogs, and yet there is a certain amount of truth in it. We may have vapor in the atmosphere, and while that vapor is visible, still the atmosphere itself is not as damp as the fogs which we get in our cities or on the top of the mountains. A fog on the top of a mountain may seem more penetrating than the fogs of the seashore, whether it is Maine or Massachusetts. The Maine climate is a changeable one. It is true generally that on nine days out of ten there is rain in some part of New England, and that it is subject to cloudy weather, owing to the frequent passage of cyclones down the valley of the St. Lawrence. But this comparison which Dr. Getchell made shows that we are not so very far behind the state of Colorado as to the total number of cloudy and partly cloudy days.

As far as game is concerned in Maine, it is surprising to me to find out how many deer are transported by the railroads. Over three thousand deer every year have been shipped by the railroads in Maine for a number of years past. These deer are only a part of the total number that are killed, and if we add the meat that is eaten in camp, there are about four or five thousand deer killed in the state of Maine every year. About one hundred and seventy-five moose are shipped by railroads in Maine. So the game supply of Maine is on the increase rather than on the decrease. There are very stringent laws, too, regarding the shooting of deer and moose out of season, there being a $1,000 fine for shooting moose in the close season. There is a $1,000 fine for a gunner killing more than one moose in a season. The state of Maine has done a great deal to preserve its natural resources; it does a great deal more than many other states in this direction. The income to the state of Maine from the visitors is considerably upwards of fifteen million dollars every year. The state of Maine is wise enough to see the necessity of doing many things for the protection and the interest of the summer visitor. They are also improving the roads of Maine, I am glad to say, through state appropriations, and this is a very valuable point.

Dr. Charles E. Nammack, of New York City, presented a paper on

NORWAY FOR NEURASTHENIA.

He described the Norway trip in summer and the geographic and climatic features of Norway. This country consists of one huge mountain mass cut through in all directions by valleys, gorges and passes, intersected again by lakes and rivers forming torrents and cataracts innumerable. The western coast, particularly at its northern part, enjoys a mild climate, like that of Christiania, twelve degrees of latitude to the south. In the interior, distant from the sea, the cold in winter is intense, and the heat in summer is equally oppressive. At Valle, latitude 59° N., altitude 1,000 feet, the range is from —31° F. to +107° F.

Norway enjoys the mildest climate of any region so remote from the Equator. Owing to the continuous daylight in the north, vegetable growth goes on with incredible rapidity. The annual rainfall on the western coast is heavy, but diminishes inland. At Bergen it

exceeds 75 inches; at the entrance of the fjord it may register 80 inches, but at the head of the fjord only 16 inches. The habits and character of the people were described, and the death-rate, aside from drowning accidents, is very low. Acute bronchial catarrhs are common, and tuberculosis holds the prominent place in mortality. Leprosy is more prevalent than in other European countries and is controlled by the state. Lepers are not allowed to marry.

In spite of a steady stream of emigration to the United States, the population of Norway has doubled in the last fifty years. The people are industrious, phlegmatic, sober, religious and contented, and a few weeks spent among them and their everlasting hills would be the best tonic for a restless, skeptical, neurotic invalid.

DR. GUY HINSDALE, of Hot Springs, Va., read a paper on

THE METEOROLOGIC AND HYGIENIC ASPECTS OF THE FLOODS IN FRANCE, IN 1910.[1]

DISCUSSION.

PROF. WILLIS L. MOORE, Chief of the United States Weather Bureau, Washington, D. C.: The paper just read was of interest to me, and I will confine my remarks to the portion that treats of the cause of the floods of the Seine. The paper states that there was a great flood in 1658. In 1658 the Seine was practically a wooded area; the economic conditions were quite different from what they are now; the valley has been divided up since and forests have been cleared away and in place of the covering of trees, there has been substituted, not a denuded region (a term so often misapplied), but another form of vegetation, — growing grass, grains, fruits and flowers. And instead of the forest area with its deep roots penetrating into the substratum, and in a way cultivating the soil, we have substituted a broken, permeable soil which is plowed and cultivated many times. Now it is significant that when the valley was entirely wooded, the flood of 1658 was higher than the recent flood. It is the history of the Danube, of which we have very good records for eight hundred years, that as the forests have disappeared and as the valley largely has been changed by the work of the husbandman from a forest area into a broken, permeable, cultivated area, the floods have consistently, persistently decreased.

The records of the government engineers of France for two hundred and fifty years, dividing that two hundred and fifty years into five fifty-year periods, show a steady decline in flood intensity in the valley of the Seine with each fifty-year period. We have records of no such length of time in this country, but for the periods for which we have records, measurements of flood heights show that there is no increase in the average height of floods or the extreme height of floods; neither is the low water lowered during the summer as the result of the cutting away of the forests. Now, this seems almost like heresy, like sacrilege of a dearly beloved theory, to express any such opinion. If you will look in the Encyclopedia Americana you will find an article of some nine or ten pages on climatology of which I am the author, in which I state that it is my opinion that there has been no change on any broad scale in the climate of the United States as a result of deforestation; that there is a better economic employment of the rain-fall by the forests; and that the cutting away of the forests augmented the floods; that they maintained better the low-water stages during dry periods, by restraining the precipitation and allowing it to slowly percolate into the soil, holding it back, decreasing evaporation. Why did I write that opinion? Simply because what I said seemed to be so truthful that it did not require demonstration.

For the last few years I have come against the most stubborn thing for a man with a theory to encounter. I have faced some bold facts that compel me to revise the old theories. Within the past several years I have discussed carefully the precipitation on many of the watersheds of great rivers of the United States. I have studied the gauge readings on these streams, and I find that there is no increase in flood intensity.

So I have been forced to the conclusion that the hand of the husbandman has transformed these valleys, these lovely plains, into as good a conserver of the moisture as the forests themselves. Here is where we have made most of our fundamental errors regarding the effects of the forests upon floods. You say, we should reforest the steep slopes of the mountain regions up at the headwaters of the mountain streams to restrain the flood. But the rain that falls on a square foot of the bank of the main stream is just as potent as same amount falling upon an equal area fifty miles away at the head waters of a tributary. It is the precipitation that falls on the total area of the basin, and if you will examine any considerable river system, — any important tributary to any considerable river system, — you will find that the area of the steep slopes in the mountains does well if it equals 5% of the total area of the catchment basin. It is the precipitation that falls on the lower reaches considerably away from the mountains that mainly causes floods, and if forests do restrain the floods, then it will be necessary for us not to reforest the area of the steep slopes of the mountains, but to reforest the great plains, and turn this region back into a condition where it will be the haunts of wild animals.

Now, then, I take the position, and have voluminous data in my possession to sustain it, that the forests really do not restrain the floods. Why? you say. Do you mean to tell us that the run-off from an open plain is as great as the run-off from a thickly wooded area? Now I answer, it depends on what you mean; it depends on which run-off you mean. Is it the run-off from a moderate rain or a shower, or the run-off from a protracted rain. The run-off from the open may exceed that from the forest in the case of showers because the forest may restrain and contain the entire rainfall when it is moderate and there be no run-off, and none of it may get over into the channels of streams, and the function of the forest is to make the low-water lower. Take two areas, one smooth as glass and the other covered by a forest; just so soon as both surfaces are saturated, the run-off is equal. Now no floods occur, barring the little, tearing, rushing creeks down steep declivities, until after all surfaces are saturated. Therefore the run-off is equal from the two surfaces at a time when floods are produced and the forest interposes no obstruction.

I have taken the average height of the Ohio River at Cincinnati for thirty-eight years. I have taken the exact gauge reading each day, and have taken the average of it for the thirty-eight years, and I will say to you that the figures stand there in my report; they are from the original records of the Weather Bureau; they show that the average for the last nineteen years is practically the same as for the first nineteen. I have taken the average high water for the four wet months of the principal rivers of the Ohio valley, including the Ohio, Tennessee and the Cumberland, and I find that the average high water for the four wet months is no greater for the last half of this period than for the first half. I have taken the average low water for the four dry months on these several rivers, and I find that the average low water shows a slightly higher flow for the

[1] See issue of this JOURNAL for Aug. 18, 1910.

last period than for the first. I have then taken two stations on the Tennessee, three on the Cumberland and five on the Ohio, and I have counted the number of days that the water was at flood stage for twenty-eight years; so for a period of twenty-eight years I counted the exact number of days at these five stations that the river was in flood. I did not assume some imaginary stage as a flood, as three different investigators who have discussed our data have done. I counted only actual floods, and I found that for the last fourteen of these twenty-eight years there was an average of forty-three days less each year when the rivers were at a flood stage than in the first fourteen years. Now I do not cite that fact to you as an evidence that there has been any such marked decrease in flood intensity as a result of the cutting away of the forests, as this statement would seem to indicate. I quote it to contravert statements of many of those interested in forestry that there has been a marked increase in flood intensity, and I quote it as a warning against making general conclusions from inconsistent or too limited data. The heavy rainfall that occurred at the time of the Johnstown flood came in the first fourteen years of this period. That enormous precipitation gave such a greater number of flood days in the first of this fourteen-year period that while the result sustains my position, I say it is hardly fair to the other side, for it is improbable that for a long time to come we shall receive such an enormous precipitation in either one of two periods that may be under discussion. Therefore, while there has been a marked decrease in flood intensity in the Ohio Valley, without a shadow of doubt, in the past fourteen years in comparison with the previous fourteen years, I do not believe that such decrease will show in the next fourteen years as compared with the present fourteen years; and I am satisfied that a proper grouping of the data will not show any such increase in flood as three different investigators think they have found. These men have taken 20 feet as a flood stage for all of the gauge readings that they have discussed, when it is a fact that at no station in the Ohio River basin is the river at flood until it passes many feet above the 20-foot stage. Now, then, if an investigator is investigating for the purpose of finding whether our floods have increased, and assumes a perfectly arbitrary stage of the river to indicate a flood, which every person living on the banks of the river knows is not a flood, what shall we say of the conclusions that are reached by such a line of reasoning?

Now there are great national problems that involve large expenditures and that seriously affect the economic policy of this nation, and will affect it for a long time to come, that are to be settled by a discussion of this problem of the floods of the rivers, and the effect of the forests upon the flood of the river. Shall it be settled by resolution of well-meaning people in open convention, or shall it be settled by the cold reasoning of men who have the statistics before them? So far, we have been educated to much that we will need to unlearn in regard to the forests and their effect upon the economic questions of the United States. I am of the opinion that long before the forests of the United States are exhausted, wood will only be used for ornamental purposes; cement, steel, iron, broken stone, all these things, are coming more generally into use. Cement houses will be of general construction. Think of the better sanitary conditions, — cooler in summer, warmer in winter, no fire loss, no heavy burden of insurance; indestructible, imperishable, — structures that practically will stand forever. Certain it is that non-combustible material is coming into use very rapidly. Long before the coal supply is exhausted, — and geologists will tell you that they can see ten thousand years' supply visible now, and they know not how much more is hidden, — but long before the coal supply is exhausted, I predict that by a wise policy of conservation, such a policy as is undoubtedly being strongly put forward by the man in the White House to-day, every natural water right will be protected and none have been sacrified under his administration, — not one. Kindly deal in facts, not mis-statements. Long before our coal supply is exhausted, by a rational conservation that shall be formulated by the engineers of the nation, by the men who are working and controlling the streams, building reservoirs, building water works, building railroads, such men will formulate a policy that will be carried out by actual working scientific men who are competent to handle these problems, and in time the rivers of the United States will heat and light your places of habitation; they will do the work of the nation; these streams, as they run down from their sources to the sea, will be utilized to heat and cook and do all the labor practically of the nation. By that time you will need no coal; by that time you will need no lumber. Any way, whether we need the lumber or not, we should not attempt to solve an economic policy by fallacious reasoning or endeavor to sustain a truth by a falsehood. The government records do not sustain the position of the enthusiasts of forestry — and there are many noble men and women concerned in forestry, and I bid them Godspeed in everything they can do to protect the great national resources, and to protect forests and grow them where they ought to be grown, and that is not where grains and fruits and flowers should grow. It is a crime to devote any acre of land in the United States to forestry that can and should grow food for the American people. I love the trees, but I love man more; I love the fruits and the flowers better, and the cereal crops better. Now we want these problems settled by such men as are gathered here, thinking men who have no personal motives, who are simply struggling as you are for the welfare of America. We want the truth, and we want a policy that shall be founded upon the truth, not simply upon undemonstrated theory.

Dr. W. F. R. Phillips, of Washington, D. C.: I think Professor Moore in his remarks has hit the nail very much on the head, and certainly his confessions as to what he said ten years ago or more is the same confession that I have to make. In a short article that I prepared for the Reference Handbook of the Medical Sciences, I stated the effects of forestation on rainfall. I did then just exactly what so many of us do — worked on the preconceived idea, and did not work with the facts. Now we medical men know what it has meant to us, every now and then, to take something for granted, but never go into the facts. We know how many of our textbooks are filled with things that are studied by us and that we have found later were not so. Some one has said that we are beginning to learn that the most dangerous knowledge that we have is not the knowledge of those things that we know are not so, and that which we accept as so and later turn out to be not so. It is a credit, I think, to the genius of that great scientist, the man who probably did more than any one else to give us a clear idea of the power of science — Darwin, in his voyage in the *Beagle*, going to parts of South America — that he saw there evidence of vegetation and trees that had disappeared; and instead of saying that the arid regions had come there because the trees had disappeared, he said that the rain had ceased falling and that is why the trees disappeared. Wise observation from the past, unnoticed, and I doubt if very many of you recall it here to-day, and yet we find that that great observer took a pretty good grasp of the situation then when he was floating around the world as a young surgeon on the *Beagle*.

Now there is another thing that, I suppose, if we had stopped and thought about it, would have put us on the right track of the relation of forestation to rain-fall, and especially to the run-off. Every person working in arid regions where irrigation has to be practiced knows that he gets the best results and keeps the water longest near the surface and, therefore, around the roots of his trees when he works that soil. I remember in Southern California, when the Climatological Society took its trip there, that, in going through the orange groves and vineyards and orchards, we were told that when they turned the water on it was necessary, in order to keep the soil moist, to keep the surface broken up, plowing it, hoeing it all the time. They had found out there that working the soil kept the soil moist, kept the water more on the surface of the earth and gave better results, and we might have thought why it was if we had just stopped for a moment to consider what it means, this breaking up of the soil. Every one of us who has had to work on a farm, and many of us probably have, has noticed in digging post-holes that as we dug down into the ground we saw little openings, veins running all around through the soil, and in watching these post-holes or walls, as many of us have, we saw that during wet weather water was pouring out of these veins. Now the result of breaking up six inches of soil on top was simply to break up the beginnings of these veins and, therefore, to delay the percolation and drainage of the water down into the subsoil, and we know to-day very well that if we want to keep the surface soil wet and want to stop evaporation from the surface, we must constantly break it up, otherwise capillary tubes are formed in the soil. So the very fact of cultivating the soil keeps more water in the soil and prevents a rapid run-off. Now, going back a little, we can demonstrate the facts; we can see that, instead of deforestation increasing floods, it really decreases them and that forestation really should increase them, because it means soil that is not broken up and, therefore, has these larger veins which carry the water down more rapidly to the subsoil and to the impermeable substrata and thence off into the river.

The effect of floods upon health, of course, is one that we are most interested in, and is one that we cannot very well discuss, that is, we cannot say very well how floods *per se* are going to affect our health at present because we have learned that a good many of the diseases, certainly the most injurious to us, come from things that the flood has directly nothing at all to do with. The fact is that we clean up after a flood. It probably will be shown in this Paris flood that the flood has, hygienically, been of not as much significance as a drought.

DR. J. H. ELLIOTT, of Toronto, Canada: This discussion has cleared up many things which were very indistinct in my mind, but there is one question I would like to ask Dr. Phillips in the absence of Professor Moore; they have explained why deforestation does not increase floods with a heavy precipitation of rain; nothing has been said of the floods due to the melting of snow. During the winter in Northern Ontario and the Northern States average precipitation of snow is about one hundred inches in the open and cultivated areas. This runs off very rapidly in the spring, as we all know, and give us spring floods. Is the flood not less in the forested area where the snow melts much more gradually?

DR. W. F. R. PHILLIPS, of Washington, D. C.: In answering the question, I would say that in case of snow it would be apparently a fact that the forests, by the shade that exists there, not very much shade, not very dense, but that such as does exist there, would interfere to a certain extent with the rapid melting of the snow. Consequently it would have the same effect as that of a gradual rain-fall producing a state such as accompanies a light rain extending over many days as contrasted with that of a rain that came up and lasted only a day or two days. We could conceive that under these conditions the per cent of forest, or anything that would shade the snow, would act in the same manner. But I think that the point made by Professor Moore was that the greatest part of the effective rain-fall was that which fell near the stream and not that which fell at a long distance. I think every one of us who has had opportunities to watch the run-off in small streams, to watch it after a thunder storm, has observed that the highest water is reached a few hours after the thunder storm and not many hours after. In other words, it shows that the run-off has come from a practically short distance, it was the near run-off. The other run-off would have come from the distant mountain, and it takes days for that water to reach the streams and produce floods; that the run-off that makes high water in a stream is really from that near it, and, therefore, the effect, so far as the practical question is concerned, of the forests in retarding the melting of the snow that existed in them is negligible.

DR. C. L. MINOR, of Asheville, N. C.: I rather fear to rise and speak after the scientific remarks of Professor Moore and Dr. Phillips, but there is one thing which I should like to ask the doctor. In our mountain region of Western Carolina the hills are covered with many beautiful forests, although these are less with the advance of the lumberman. All through these forests there is a dense, thick, undergrowth with laurel and rhododendron and moss and dead leaves still, probably, as primitive as it was in the days of Moses. At any time of the year if you go in these forests and examine the soil under these trees you will find it damp and moist, and when the rains fall they do not rush out from the woodland fastnesses (although the mountain streams, it is true, swell), but to an ignorant layman seem to be taken up and held back by the undergrowth, which in turn is protected by the forest in which it grows. But where our lumbermen have been active and have bared our hillsides, as they have also in parts of Central Pennsylvania, the soil is not moist save immediately after a rain, the streams do not run even in the driest weather as they do in the forests, but we find only dry beds, and when the rains come you see the water tearing down the hillsides, gullying them, washing them out, not sinking into the soil, which will be bone dry the day after such a rain, but going down to swell our rivers and raise them to flood height, destroying the property along their banks.

Such are the results of my ignorant observations, but after I hear Professor Moore and Dr. Phillips, who tell us that the forests can have no possible effect of this sort, I wonder if it would not be wiser for us to bare all our hills of trees, to get rid of all our forests and to trust to the professor's theories to protect our lowlands and to give a steady supply of water to our mills.

DR. W. F. R. PHILLIPS, of Washington, D. C.: I would suggest that if the forests are in the same condition that they were at Moses' time at the present time, and have been so during the interval, if he could only give us the records and actual measurements throughout that long period we might change our views again. I know I have changed mine, and the Chief of the Weather Bureau has changed his; we have both changed our views. I think the explanation, however, of Dr. Minor's difficulties could be found. First, before I would attempt to explain things, I would ask him to bring the records, the actual measurements, because sometimes local floods occur simply because a very heavy thunderstorm occurred just over the region in

question, and it may be a coincidence that two or three storms occurred over a particular region, and they got a flood there; also when trees have been cut away you observe these floods more than when the trees are thick. If they are just as Moses left them, who has been there to see whether the storms are high or low? If the doctor will have the measurements given to us, we will try to explain it. I know — we all know — that, just working on your impression, taking some man's impression for a fact, is not satisfactory, and every now and then we have to go over and change our impressions.

Dr. C. L. Minor, of Asheville, N. C.: Then you will admit that the water runs off faster from these forest-clad hilltops than it runs off the open?

Dr. W. F. R. Phillips, of Washington, D. C.: In about half an hour after a heavy rain the surface soil is all permeated and for all intents and purposes it is the same whether it is forested or deforested. A half an hour of rainfall and the run-off will depend entirely upon the slope rather than anything else.

Dr. Minor: It seems to me we should pray for rain and take the trees up at the foot of the hills as they are washed out.

Dr. Hinsdale: I only wish to thank Professor Moore and say that I appreciate his coming here to add so much to the interest of this subject which I introduced.

(To be continued.)

Book Reviews.

Bier's Textbook of Hyperemia, as Applied in Medicine and Surgery. By Prof. Dr. August Bier, of Berlin. Only authorized translation from the sixth German revised edition by Dr. Gustavus M. Blech, Professor of Clinical Surgery, Illinois Medical College; Dean and Professor of Surgery, Practitioners' School of Medicine; Surgeon-in-Chief, Practitioners' Hospital, Chicago; Member American Medical Association, Association of Military Surgeons of the United States, etc. With 39 illustrations. New York: Rebman Company.

Bier's "Hyperemia" was popularized in America by Meyer and Schmieden, the authorized exponents of Bier's work. We doubt if Bier's own book in its English dress will add greatly to interest in his methods. Whether so or not, this book sheds light on the man, on his personality, his convictions, his enthusiasm and his egotism. The translation is fair, but the book itself is prolix and the style labored. The best part of it is the introduction, — a readable, philosophic treatise on biologic science and the application of hyperemia to morbid conditions. The next most interesting section of the book is an informing appendix of ten pages, thrust into the middle of the volume, and dealing with the "influence of the total blood for curative purposes." In this little appendix the author reviews luminously the status of cellular pathology and the new humoral pathology.

The book is an octavo of four hundred and thirty-nine pages. Half of it deals with the general principle of active and passive hyperemia; half of it with the practical application of hyperemia to special lesions. As a whole, the book is extremely informing and will be read with pleasure by earnest students of surgical literature.

Lectures on Surgical Nursing. By E. Stanmore Bishop, F.R.C.S. Eng., Honorary Surgeon, Ancoats Hospital, and Gynecological Surgeon, Jewish Memorial Hospital, Manchester; Member of Council, Obstetrical Section, Royal Society of Medicine. Illustrated. William Wood & Co. 1910.

This is a delightful little pocket manual full of information for the surgeon as well as for the nurse. It is a collection of the author's addresses to nurses, and tells nearly all that the nurse can wish to know on the subject through the medium of reading. Moreover, the book itself is most readable; it is short, pithy, luminous and pleasant.

Practical Suggestions in Borderland Surgery. For the Use of Students and Practitioners. By Gustavus M. Blech, M.D., Professor of Clinical Surgery, Medical Department, Loyola University; Director-in-Chief, Illinois Legion American Red Cross; Surgeon-in-Chief, Abraham Lincoln Hospital, Chicago, etc. Philadelphia: Professional Publishing Company. 1910.

This is an interesting little brochure for students and general practitioners. It is rendered somewhat irritating by a needlessly laudatory publishers' introduction. It is extremely well conceived, however, and is carried out in an excellent, liberal spirit. Blech protests that the noble art of surgery is being debased by hosts of hasty and incompetent operators. "This is a surgical age," he tells us; "the recent graduate hangs out his shingle, and from now on has but one aim, — to operate; the exceptions only prove the rule. Men like the late Senn have tried in vain to stem the tide of this gigantic wave, which he has aptly called *furor operativus*." The author continues through eleven admirable chapters to discuss types of medical and surgical ailments; to point out those which are suited to various therapeutic measures, and to describe operations suitable to the various lesions. He debates especially the dangers incident to operations in general, and their reduction to the minimum; contra-indications to operations in general, and the surgeon as a factor in successful surgery. The book is cheaply constructed, but is sold for $1.50, and is well worth the reading.

The Practitioner's Case Book. Prepared and arranged by the editorial staff of the *Interstate Medical Journal*. St. Louis: Interstate Medical Journal Company. 1910.

This book provides the busy general practitioner with a convenient and systematic form for recording and preserving clinical histories. The appended charts should be particularly useful for graphic indication of the data of physical examination.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, NOVEMBER 3, 1910

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

THE CAPTAIN OF THE HOSTS OF DEATH.

THE bulletin of the United States Census Bureau on mortality statistics for the year 1909, recently published, makes rather interesting and in some respects discouraging reading. In spite of all that has been said and done in the conflict against tuberculosis, that disease still stands first as a cause of death in this country. The registration area, from which the figures are taken, represents over 55% of the estimated total population. In this area, among "gainfully employed or occupied males," pulmonary tuberculosis caused 14.8% of all deaths, heart disease 11.9%, accidental violence 10.5%, Bright's disease 8.5%, pneumonia 8%, apoplexy and paralysis 7.3%, cancer 5.5%, suicide 2.6% and typhoid fever 2.2%. Among occupied females the percentages of causation were, pulmonary tuberculosis 21%, heart disease 10.3%, cancer 8.1%, Bright's disease 7.3%, pneumonia 7%, apoplexy and paralysis 5.9%, accidental violence 3.2%, typhoid fever 2.8%, suicide 1.6%. Deaths from cardiac and renal disease, then, from pneumonia and cerebral hemorrhage, are slightly commoner among men than among women; deaths from tuberculosis and cancer are nearly 50% commoner among women than among men; and among men deaths from suicide are 50% more frequent and deaths from accident over 200% more frequent than among women. These figures for tuberculosis make it seem as though the efforts of the past ten years to suppress this disease had been almost of inappreciable effect. With reference to occupation, it appears that printers, lithographers and pressmen have the highest mortality from tuberculosis, amounting to 51.5% for the age-period from twenty-five to thirty-four; farmers for the same period have a mortality from tuberculosis of 26.2%, and machinists (the lowest) of 25%. With reference to age, it is found that for all occupations the highest mortality from tuberculosis occurs in the decade from twenty-five to thirty-four; after which there is a rapid and accelerating decline. The much greater prevalence of tuberculosis among women than among men is noteworthy. There seems no obvious or satisfactory reason for the relatively high immunity to tuberculosis of machinists, whereas that of farmers is easily self-explanatory on account of their outdoor mode of life. All these facts must give us pause, and should make us realize that perhaps we are still far from understanding the real nature of susceptibility to tuberculosis, and that the progress of the natural history of some diseases may be far less influenced than we are wont to imagine by our hygienic, prophylactic and sanitary measures.

INCREASE IN DEATHS FROM HEART DISEASE.

DR. GUILFOY has just issued a statement in which he calls attention to the fact that twice as many persons, in proportion to the population, are now dying from diseases of the heart in New York as thirty-three years ago. In 1876 there were 1,131 deaths from this cause in the city, a death-rate of 82 per 100,000 of the population, and last year, 6,639 deaths, a ratio of 161 to the 100,000. The figures thus far in 1910 indicate a further increase when the vital statistics of the year are complete. Every year the death-rate from cardiac disease is increasing, and unless something is done to check this it will become more of a menace than tuberculosis or acute respiratory diseases, which now lead as the principal causes of death. At the present time it ranks as third in importance, and what is true for New York is for the most part true of the country at large. As Bright's disease is so frequently associated with heart disease, it is essential to consider this in connection with the latter. Here also the death-rate has doubled in New York. In 1863 there were only 640 deaths from this cause, a death-rate of 53 per 100,000, while in 1909 these were 4,655 deaths, a rate of 113 per 100,000. As with heart disease, the increase has been the most marked in the last twenty years. As to the causes of this increased mortality, Dr. Guilfoy assigns

an important part to the grippe bacillus, to which he attributes many deaths from cardiac disease. Of far more importance, however, are the present conditions of living. In a large proportion of the population it is the more luxurious mode of life; eating too much nitrogenous food, drinking too much and taking too little exercise. In other instances life is more intense and the struggle for existence more difficult. In a word, people are living "faster" than they did twenty years ago. He is of the opinion that if they would eat less, drink less and exercise more in the open air, the death-rate from heart disease would take a decided drop.

SUCCESS IN ATHLETIC SPORTS.

In a recent paper before the American Academy of Physical Education Dr. Dudley A. Sargent, of Cambridge, undertook to explain the usual superiority of women over men in swimming on the basis of their better conservation of heat, owing to their usually greater proportion of adipose in proportion to body weight and bulk. On the same basis he would explain the physical superiority of girls to boys during a certain period of adolescence, and the familiar ability of women to endure cold in evening dress better than men. So far as the latter point goes, it must be remembered that habit probably plays a large part. The converse of Dr. Sargent's first proposition, however, seems the truer form of statement. The professional male swimmer may be inferior because he trains down too lean, like a land athlete who "gets fine" or "goes stale" before an event. Probably overtraining, with its loss of weight and associated nervous strain, is more often responsible for the failures of male athletes than any other one thing.

The athlete, in any case, is an artefact, a man unnaturally developed to make an abnormal physical exertion. The reason the English succeed better in sports than any other nation is because they train for them the least and take them merely as pleasurable incidentals in an active outdoor life. It has been said recently that a good athlete may make a poor soldier, but that a good soldier will generally make a good athlete. Discipline of temperament is worth more than specific physical training. In the long run, the person to succeed in any test of endurance, be it man or woman, will be the one who in addition to an organically sound and normally exercised body, whether stout or lean, has an orderly and persistent mind to govern it.

DANGERS OF EPIZOOTIC ANTHRAX.

The occurrence last week of a case of anthrax in Boston recalls the serious possibilities of even the sporadic presence in a community of this fatal disease. An example of these dangers was shown in the outbreak of anthrax at Chicago during July and August of the past summer. The infection appeared among the cattle of about twenty farms in three nearby towns from which a large part of the milk supply of the city was derived. Eighty-seven cows died of the disease. Immediate measures were taken by the Chicago Board of Health to prevent spread of the infection by the milk, with the result that a general epidemic was averted. One of the farm owners did become infected and died. The measures adopted are described in a recent bulletin of the Board of Health. All sick animals were isolated, all exposed animals quarantined, and all others treated with standard anthrax vaccine. All dead animals were burned or were buried eight feet deep, the grave and ground about strewn with quicklime and sprinkled with strong corrosive sublimate, and the site fenced to prevent other animals from grazing there. The milk from every infected herd was withheld from market until a suitable period after the last death from the disease. That these measures were effective is shown by the prompt and complete suppression of the epizoötic. Their adoption might at any time become necessary in our own community in the event of the appearance of anthrax among cattle of the vicinity.

CONTINUANCE OF THE DROUGHT IN MASSACHUSETTS.

In recent issues of the Journal we have given some account of the water famine in Palmer, Mass., and of the measures taken to meet it. Meantime the drought in Massachusetts has continued and several other towns are now threatened with serious scarcity in their water-supply. This deficiency extends also to other New England states. Not only has the shrinkage of streams diminished the amount of drinking-water, but in some cases has caused the shutdown of large mills from failure of power, with consequent non-employment and hardship for hundreds of mill-hands.

In many places artesian wells have been sunk to supplement the drinking supply and guarantee against absolute famine. At Spencer, Mass., a special meeting has been called to discuss the situation, which is considered one of real gravity.

At Peabody, Mass., the inhabitants for a time drew on Suntaug Lake, or Humphrey's Pond, which supplies the neighboring town of South Lynnfield, but the rapid decline of water in this lake to 100 feet below high-level mark led them to desist, and they have now established an auxiliary pump at Spring Lake.

The total rainfall in Boston this year thus far is only 22.2 inches, an amount far below the average; and although this city is of course in no immediate danger, the situation outside the metropolitan district may become serious unless there is considerable precipitation before the onset of winter.

SUBSTITUTES FOR THE PUBLIC DRINKING CUP.

THE mere passage and literal enforcement of a good law may avail little unless the spirit of its provisions be also carried into effect. It is now a month since the regulation went into force in Massachusetts forbidding the use of public drinking-cups. Such cups seem uniformly to have disappeared, but adequate substitute for them has often not been provided. In some places bubbling fountains have been established; in a few, individual paper cups are obtainable; others have cut the Gordian knot by removing the water-cooler altogether. In many instances, however, the public cup has merely been taken away and the water left, with the natural and inevitable result that those who wish to drink apply their mouths to the faucet and ingest the fluid by suction, a practise even more disgusting and dangerous than the use of the common drinking-cup.

No doubt in many of these places other provision will soon be made. Others may be waiting to see which way public opinion will turn. Meantime the hygienic, or non-hygienic, result is the same. On the whole, the slot-machine method of furnishing individual paper cups at public drinking places seems the best, but some method there should be. Statutory abolition of the common cup should be accompanied by provision of a suitable substitute therefor.

DR. GRENFELL AND HIS WORK.

FEW modern stories read more romantically than that of Dr. Grenfell's labors among the natives of Labrador and the north. His life among them includes not only all the varied excitements of a doctor's experience, but those of a hunter, of a seaman and of an explorer as well. Among the primitive people with whom he deals emotions are simple, but genuine and poignant; and he has opportunity, as we of more civilized environment do not to the same extent, to see man and nature in elemental relations. That such experience should have not only increased his faith and deepened his ardor of service is a tribute both to him and to humanity. The picture which he draws, in a recent newspaper article, of hardship and disease among the "desolate ice-isles of northern seas" is thrilling in its suggestions of adventure and heroism. Dr. Grenfell is one of those figures who have appeared at every stage of our racial progress exemplifying the indomitable roving adventurous instinct of our people associated with the highest ideals of devotion to duty and to the romance of righting wrong and relieving human distress.

MEDICAL NOTES.

PLAGUE IN VENEZUELA. — Report from Venezuela states that four new cases of bubonic plague have occurred during the past week at Caracas, but that there is no spread of the infection elsewhere in the state. In Caracas the theaters and other places of assembly have been closed and all public meetings forbidden for the present.

OPIUM SANDWICHES IN CHICAGO. — A new method of evading the law relative to the sale of opium is reported from Chicago, where the proprietor of a Chinese restaurant has recently been discovered purveying sandwiches containing the drug to habitués who had difficulty in obtaining it in the more usual form.

REPEATED MULTIPLE PREGNANCIES. — It is reported from Cleveland, Ohio, that, on Oct. 21, Mrs. William G. Clark of that city gave birth to her third set of triplets. She has been twice married. By her first husband she is said to have had two pairs of twins and one set of triplets, and by her second she has had two other pairs of twins and two sets of triplets, making in all seventeen children in seven pregnancies. The sexes are not stated. Mrs. Clark was herself the only girl in a family of twenty-one children.

HEALTH CARAVANS IN ENGLAND. — During the past season a so-called health caravan has been sent from town to town through certain parts of England by the Women's Imperial Health Association of Great Britain, giving lectures and practical demonstrations, illustrated by the cine-

matograph, on various topics of hygiene. The work of this caravan, the *Amora*, has been so satisfactory that two others are to be sent out, one in London and one in the eastern counties.

Communicability of Fish Cancer. — On Oct. 27, seven dogs, habituated to a fish diet, were sent by the bureau of fisheries at Washington, D. C., to the hatcheries in the state of Maine for use there in experimental study of cancer. The dogs will be fed on cancerous fish in the effort to determine whether fish cancer be communicable to other animals through the medium of food.

Organization against Tuberculosis. — The rapid spread and elaboration of the campaign against tuberculosis is illustrated by comparison of the numbers of institutions established for its prosecution. In 1904 there were in the United States 133 sanatoria and hospitals for tuberculosis, 32 special dispensaries for its treatment, and 39 anti-tuberculous organizations. There are now over 400 such sanatoria and hospitals, over 300 tuberculous dispensaries, and 450 anti-tuberculosis associations.

Some Living Centenarians. — Four of the inmates of the Home of the Daughters of Jacob, in New York City, are alleged to be over one hundred years old. At a recent fire in the institution these reputed centenarians, three women and one man, were all safely rescued.

Mrs. Lydia Shepard, of Millville, N. J., is said to have been born on Oct. 22, 1809. She is reported to be in excellent health and does active work about the house.

Mrs. Caroline Jones Hudson, of Templeton, Mass., is said to have been born on Oct. 30, 1808. Genealogic records indicate that several members of her mother's family were also centenarians. It is stated that she had sixty-eight cousins, of whom only one still survives.

Relative Percentages of Suicide. — Statistics recently published in Kobe, Japan, compare the frequency of suicide in that country with that among some of the occidental nations. During the twenty-two years from 1887 to 1908 inclusive, the average annual suicide-rate per million inhabitants was, in Denmark 253, in France 218, in Switzerland 216, in Prussia 197, in Japan 184, in Austria Hungary 159, in Belgium 122, in Sweden 119, in Bavaria 118, in Great Britain 80, in Norway 80, in Holland 58, and in Italy 52. Undoubtedly suicide is increasing in every country where civilization is progressing. Interesting as these figures are, they however afford no explanation of the reason for the very high percentage in Denmark or for the relatively and gratifyingly low percentage in England, Norway, Holland and Italy. Probably the increase of suicide, like the decline of the birth-rate, depends on subtler facts of racial character than can be analyzed by statistics.

The Cholera Epidemics. — The Italian epidemic of cholera seems to be distinctly waning. During the week ending Oct. 29, 48 new cases and 28 deaths were reported. News from Victoria, B. C., however, states that a serious epidemic of the disease has broken out in central Japan. Several hundred cases have been reported at Kobe, and over 100 are said to be now under treatment at Osaku. In the United States no more cases have occurred, though several suspects have been held under observation. For the purpose of tracking possible cholera carriers, the immigration officials, acting on the counsel of Dr. William K. Rucker, of the United States Public Health and Marine-Hospital Service, have adopted the plan of registering on a special card the intended destination of every immigrant landing here from an infected port. These cards, forwarded to state and local boards of health, afford means of keeping track of every immigrant, in the event of a possible subsequent recrudescence of a latent infection.

Boston Charity in Ireland. — Over a year ago the Countess of Aberdeen, whose charitable zeal has done so much to relieve and educate the Irish people, visited Boston for the purpose of raising funds for a tuberculosis preventorium, projected by the Women's National Health Association of Ireland. This Sutton Holiday Home and Preventorium was completed and opened in August, 1909, and its first annual report shows that during the past year it has received 125 inmates,—75 adults and 50 children. It is situated on a hill near Howth, a suburb nine miles from Dublin at the northern angle of Dublin harbor, overlooking the rugged Irelandsey or Isle of Ireland, which faces Anglesey, across the Irish Sea. The site is attractive and the climate salubrious, and the institution gives opportunity for the poor and ill-fed from the overcrowded districts of Dublin to obtain for a time rest, good food, fresh air and training in the desirable hygiene of life. No patients are received except those who are free from tuberculosis but whose

environment and physical condition make them seem susceptible subjects for infection. It is pleasant thus to learn of the good work of an institution to which large subscriptions were made by Boston charity.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.— For the week ending at noon, Nov. 1, 1910, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 36, scarlatina 46, typhoid fever 19, measles 7, smallpox 0, tuberculosis 52.

The death-rate of the reported deaths for the week ending Nov. 1, 1910, was 16.49.

BOSTON MORTALITY STATISTICS.—The total number of deaths reported to the Board of Health for the week ending Saturday, noon, Oct. 15, 1910, was 205, against 181 the corresponding week of last year, showing an increase of 24 deaths, and making the death-rate for the week, 15.94. Of this number 109 were males and 96 were females; 200 were white and 5 colored; 138 were born in the United States, 64 in foreign countries and 3 unknown; 51 were of American parentage, 126 of foreign parentage and 28 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 33 cases and 3 deaths; scarlatina, 9 cases and 0 deaths; typhoid fever, 30 cases and 2 deaths; measles, 4 cases and 0 deaths; tuberculosis, 42 cases and 22 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 25, whooping cough 2, heart disease 31, bronchitis 3. There were 16 deaths from violent causes. The number of children who died under one year was 50; the number under five years, 64. The number of persons who died over sixty years of age was 46. The deaths in public institutions were 83. Anterior poliomyelitis, 1 case and 1 death.

Of the above infectious diseases the following were non-residents: Consumption, 3 cases and 5 deaths. Scarlet fever, 1 case. Typhoid fever, 1 case.

Deducting deaths of non-residents, the total is 174 and the death-rate is then 13.53.

FREE HOSPITAL FOR WOMEN. — Invitations have been sent by the Trustees of the Free Hospital for Women for the inspection of the hospital buildings this afternoon from two until six.

FINES FOR ILLEGAL SALE OF MILK. — In the Roxbury District Court last week six local dealers were fined a total of $225 for continuing to offer milk for sale after their licenses to do so had been revoked.

A WEEK WITHOUT DEATH FROM DIPHTHERIA OR SCARLET FEVER. — It is worthy of notice that, during the week ending Oct. 22, no death from diphtheria or scarlet fever was reported to the Boston Board of Health. It is several years since a week has elapsed without a death from either of these diseases in Boston.

PENALTY OF BREAKING QUARANTINE. — In Malden, Mass., last week a patient with diphtheria, who had been duly quarantined at her home, refused to stay indoors and attempted to travel on an electric car. She was promptly removed by the board of health to the local hospital for contagious diseases.

ADDITION TO MILFORD HOSPITAL. — It is announced that on account of the present overcrowding of the Milford (Mass.) Hospital, which was established some years ago by Mr. and Mrs. Eben S. Draper, of Hopedale, Mass., Mr. Draper has recently offered to provide for the erection of a new ward to accommodate twelve patients and five attendants.

CONTINUED CONDEMNATION OF OYSTER-BEDS. — In recent issues of the JOURNAL we have noted the condemnation by the Rhode Island Board of Shellfish Commissioners of various oyster beds in that state. During the past week nearly 200 more acres of beds have been condemned along the Kickomesit River, near Fall River, Mass. It is stated that the sewage from that city is the source of their pollution.

CALVES CONDEMNED AT BRIGHTON. — At the Brighton slaughter-yards last week, the agents of the Boston Board of Health condemned, as unfit for food, 82 out of a shipment of 84 calves. Many of these animals were said to be only two or three days old. This is said to be the first instance in Massachusetts of such condemnation of bob-veal.

A SECOND HOOKWORM CASE IN BOSTON. — A second case of uncinariasis was discovered in Boston last week in the person of a young Chinese immigrant, who had come from Hongkong to Vancouver and thence to Halifax and had arrived in Boston from the latter city a few days ago. The patient has been sent to the Carney Hospital. His infection with the hookworm must of course have occurred in China.

A Centenarian. — Mrs. Mary Turcotte, who died on Oct. 23, at Brockton, Mass., is said to have been born on Oct. 1, 1810, at Lavaltorie, P. Q., Canada. She was the mother of five children, of whom two survive her. It is alleged that for the past fifteen months she had hardly slept at all, notwithstanding which she had maintained good health and continued to discharge her domestic duties until partly paralyzed by a cerebral hemorrhage last spring.

Consumptives' Hospital Out-Patient Building. — In a recent letter to the mayor, Mr. Edward F. McSweeney, chairman of the board of trustees of the Boston Consumptives' Hospital Department, urges the erection of a new out-patient building for the hospital. During the past year about 3,000 cases have been referred to the present out-patient building on Burroughs Place, over 10,000 visits have been made there by patients, and 8,000 homes have been visited by the district nurses doing the work of the department.

Duties of the People to the Board of Health. — Under the auspices of the Boston Hygiene and Sanitation Society, there was held one evening last week at the North Bennet Street Industrial School a meeting of residents of the North End. An address was made by Mr. John Ritchie, Jr., on familiar subjects of hygiene, with special emphasis on the duties of the people to help themselves in such matters and to assist the efforts of the Board of Health in their behalf.

Growth of Free Hospital for Women. — The annual meeting of the Brookline Free Hospital for Women was held in Brookline, Mass., last week. The report of the visiting surgeon showed that during the past year the average number of occupied beds in the institution has been increased from 30 to 36, and that 123 more patients have been admitted and treated than during the preceding year. In view of the large waiting list of patients, whom even this increase could not accommodate, the trustees then voted still further to enlarge the number of beds to 40.

Inspection of Factories, Workshops and Public Health. — At hearings held last week at the State House before the special commission appointed "to investigate the efficiency of Massachusetts laws relative to the inspection of factories, workshops and public health," complaint was made by several medical inspectors that many of their duties required special mechanical knowledge which they could not be expected to possess, and that these duties take time from others more legitimately within their province. It seems likely that present methods of inspection may be radically changed in the near future.

Demonstration of Radio-active Preparations. — The annual meeting of the stockholders of the Institution for Physical Therapeutics will be held in Boston on Nov. 7. This meeting "will be followed by a demonstration of radio-active preparations, including the radiogen-schlamm for the local treatment of articular and muscular rheumatism." The preparations to be shown have been imported from the Radiogen Gesellschaft in Charlottenburg, Germany. The demonstration should be of particular interest in view of the recent special meeting of the Suffolk District Medical Society on the subject of radio-activity and its therapeutic applications.

The Horns of the Doctor's Dilemma. — At a meeting last week of the Channing Club in Boston, Dr. Richard C. Cabot gave an address on "The Doctor's Dilemma," in which he depicted the passing of the general practitioner, the family physician, crowded out on the one hand by specialists, on the other by the development of large public hospitals with their provisions for caring promptly and efficiently for the sick. Perhaps the public is pecuniarily, if not morally, the gainer by this process of hospitalization. The doctor to whom the dilemma is presented, however, might contemplate it with more equanimity if the extinction with which he is threatened really represented the achievement of the ideal of our profession,—to learn how men should live so that there might be no more sickness.

Massachusetts State Conference of Charities. — The eighth annual meeting of the Massachusetts State Conference of Charities was held on Oct. 26, 27 and 28 at Fitchburg, Mass. One of the principal topics under discussion was the care of the insane and the treatment of mental diseases. Dr. Owen Copp, of the Massachusetts State Board of Insanity, reviewed the history and prospects of the subject in a paper on "Mental Disease in Retrospect and Outlook in Massachusetts." Dr. Elmer E. Southard described "The Purposes of the New State Psychopathic Hospital at Boston," the project for whose establishment is still before the legislature. Mr. Edmund A. Whitman, of Cambridge, presented a paper on "Industrial Activities for the State's Dependents."

At the closing session of the conference Dr. H. Lincoln Chase, of the Brookline Board of Health, spoke on "Co-operation in the Community for the Public Health."

ABATEMENT OF POLIOMYELITIS. — At the quarterly meeting of the Massachusetts Boards of Health, held in Boston last week, a paper was read by Dr. Robert W. Lovett on poliomyelitis, and there was considerable discussion of the epidemics of the disease that have prevailed during the past summer. At present the spread of the infection seems to be abated by the advent of cooler weather. During the past week there has been one death from it at Malden, Mass., and in Rhode Island only one new case has been reported. There has now been reported a total of 205 cases in Rhode Island, with 23 deaths. Of these, 79 cases and 12 deaths have occurred in Providence; 19 cases and 3 deaths in Newport; 12 cases and and 1 death in Woonsocket; and in Pawtucket, 12 cases but no deaths. It is expected that the epidemics are practically at an end for the present season.

NEW YORK.

ADVISORY BOARD OF STATISTICIANS, CITY HEALTH DEPARTMENT. — The first formal conference of the Advisory Board of Statisticians of the City Health Department was held on Oct. 28, when plans for work to be carried out next year were discussed. This board was appointed by Commissioner Lederle in July last, and its members are to serve without compensation. On it are Dr. Roger S. Tracy, former registrar of the Health Department; Dr. William H. Guilfoy, the present registrar; Dr. Cressy L. Wilber, chief of the Statistical Bureau of Commerce and Labor, Washington; Prof. C.-E. A. Winslow, of the College of the City of New York, formerly of the Massachusetts Institute of Technology; and Prof. Walter F. Wilcox, of the Department of Economics, Cornell University, the consulting statistician of the New York State Department of Health.

THE DROUGHT AND WATER SUPPLY. — The President of the State Board of Water Supply, accompanied by the consulting engineer of the board, has been making a tour through Westchester County in connection with the water supply problem occasioned by the long-continued drought, and they found the condition at Yonkers serious, the reservoirs containing but little more water than previous to the recent rainfalls. On Oct. 27 a conference was held by the Public Safety Commissioner, the local health officer and the city chemist regarding the condition of the water in the reservoirs, and the residents were urged to continue to boil the water before using.

THE STRAUSS MILK DEPOTS. — As the result of a conference with the committee appointed at the meeting of philanthropic agencies on Sept. 7, Nathan Strauss has now consented to keep open his eight all-the-year-round milk depots. In the interview with Mr. Strauss which the committee had at the residence of Dr. A. Jacobi on Oct. 24 at which he announced his consent to carry on the work, Mr. Strauss expressed the hope that as a result of the activity of this committee and others many additional infants' milk depots would soon be established, and also that ultimately the city would undertake this work to as large an extent as might be required.

TYPHOID FEVER. — One of the first acts of the new Governor, Horace White, succeeding Governor Hughes, has been to request the Health Commissioner, in view of the prevalence of typhoid fever throughout the state, to keep in close touch with the situation and take every precaution to prevent the spread of the disease. While no epidemic of large proportions has been reported, so many cases have developed that the governor is convinced that the present situation warrants the utmost vigilance on the part of the State Health Department. At the same time in New York, Edward Hatch, Jr., chairman of the State Water Pollution Commission, has called the attention of the public to the danger of typhoid after a protracted drought, when the first heavy rains are apt to wash down the filth which has accumulated upon the watersheds. In this connection he suggests that boiled Croton water is preferable to a bottled water whose proprietors in this dry season may be obliged to fill their orders from a source other than the spring.

FEWER DEATHS FROM TYPHOID FEVER. — Dr. John S. Billings, Jr., of the Health Department, has made a special report to Commissioner Lederle in which he states that the figures show that in the first nine months of the present year there have been fewer cases of typhoid fever and deaths from the disease in Manhattan than during the corresponding period in any of the last five years. The death-rate from typhoid for the three quarters of 1910 is 13.6 per thousand, as compared with 15.1 for the years from 1905 to 1909 inclusive. The greatest prevalence of the disease was in the year 1907, when 2,387 cases were reported,

with 372 deaths. The present year there were 1,268 cases, with 172 deaths. "These figures," continues the report, "bear out the statement that there is no unusual increase in the prevalence of typhoid fever. The disease is more prevalent through New York state, Connecticut and Rhode Island, but not to any alarming extent." In New York City in the week ending Oct. 8 there were 17 deaths from typhoid, as against 24 in the corresponding week of 1909, and in the week ending Oct. 15, 20 deaths, as against 13 in the corresponding week of 1909.

Mortality from Typhoid Declining. — The State Commissioner of Health has submitted to Governor White a report on typhoid fever in the state during the past ten years, in which he gives the following figures:

Month.	Average number of deaths, 1900 to 1909 inclusive.	1910.
January,	126.6	87
February,	107.1	87
March,	108.2	92
April,	94.4	68
May,	92.0	63
June,	74.4	70
July,	106.2	94
August,	153.9	131
September,	192.6	183

"From these statistics," the commissioner says, "it is evident that the normal variation of typhoid fever during the year is quite marked. The mortality from typhoid fever for the state during 1910 is appreciably below the average for the last ten years, and for the past three months for which statistics are available, namely, July, August and September, is approximately 10% less than normal. In the cities of the state, typhoid fever has during the past three months been in excess of the average only in three districts, the Adirondack and Northern, the Eastern Central and the Southern Tier districts. It was found, further, that of these districts only in the case of the Eastern Central District was typhoid fever appreciably in excess." He adds that Yonkers and Niagara also have an unusual number of cases of the disease, and that the conditions at Yonkers have recently been investigated by the State Department of Health. He then goes on to say: "It is not generally understood that typhoid fever is considerably more prevalent in the late summer and fall months of the year; consequently, as the fall approaches, public anxiety is unnecessarily aroused, and often gross exaggerations are prevalent as to serious epidemics, which are attributed to remote if not entirely erroneous causes."

The City's Budget. — The tentative budget for the city's expenses, which is usually accepted as final, has been agreed upon by the budget committee of the Board of Estimate and Apportionment. The total is $171,505,787, or more than $8,000,000 more than the expenditures in 1910. In 1911 the Department of Public Charities is to receive $2,838,446, an increase of $155,834; charitable institutions to which the city gives more or less support, $4,598,575, a decrease of $135,077; the Tenement House Department, $811,412, an increase of $21,690; Bellevue and Allied Hospitals, $1,196,065, an increase of $54,005; the Board of Ambulance Service, $27,950; the Department of Health, $2,823,499, an increase of $75,776. The original estimate of the Health Department was $1,253,198 greater than the amount allowed.

The State Water Supply Commission has approved the deep-rock pressure tunnel for the distribution of the supply from the new Catskill Aqueduct, stating that the plans for its construction of the City Board of Water Supply, which is building the aqueduct, are justified by public necessity. The Board of Estimate and Apportionment had already approved the tunnel, which will pass under the Borough of the Bronx, the Harlem River, Manhattan Island and East River, with mains leading through Brooklyn to Queens and under the Narrows to Richmond (Staten Island). The estimated cost of the work is $25,000,000.

11. Amberg, E. *Guide for the Lateral Sinus Line.*

10. Fox reports a case of tetanus in a boy of twelve. The period of incubation was eleven days, at the end of which time stiffness of the jaw appeared. The next day tetanic convulsions developed. The following day the wound was cauterized, — 3,000 units of antitetanic serum

were given subcutaneously and 1,200 into the spinal canal. After this, 3,000 units were given every six hours, first subcutaneously, later intravenously. Increasing doses of bromide and chloral were given every four hours and morphia, gr. ¼, by mouth every evening. Four days after symptoms first appeared it was decided, as the patient continued to grow worse, to use magnesium sulphate intraspinally. Two cubic centimeters of the cerebrospinal fluid were withdrawn by lumbar puncture and an equal amount of a 25% solution of this salt was injected. Four hours after this injection, all four extremities had become very much relaxed, and from this time on the patient steadily improved. In all, he received 60,000 units of tetanus antitoxin — 24,000 intravenously, 12,000 intraspinally and the rest subcutaneously. [L. D. C.]

9. ASTLE, C. J. *A Case of Hyperchlorhydria Apparently Relieved by the Use of Prisms.*

4. Kopetzky reports fifteen cases of purulent otitis media treated with autogenous vaccines. He concludes that such vaccines are valuable in cases where subsidence of bacterial activity means the end of the lesion. In acute cases, after the period of violent onset with constitutional symptoms has passed, the added immunity acquired through vaccine therapy seems rapidly to cure the diseased ear. In cases with bone lesions the vaccines had no effect. [L. D. C.]

1. Herrick claims that with true organic cardiovascular angina pectoris there cannot always be made out peripheral arteriosclerosis, cardiac hypertrophy and high blood pressure. The finding of aneurysm or lesion of the aortic valve does not exclude angina, but rather argues in its favor. Attacks are not always few in number and brief in duration; they do not occur solely after exertion. While the prognosis is grave, life is not necessarily limited to a few months. The disease is not to be excluded because the symptoms occur in women, even in nervous hysterical women. The pain is not necessarily severe; it may be mild or even lacking. Digitalis is not necessarily contra-indicated; it is often of great value.

2. Conner emphasizes the very important facts that in locomotor ataxia a loss of the normal sensibility of the viscera sometimes occurs, and in such cases acute inflammatory diseases of the abdomen, such as appendicitis or peritonitis, may develop and run their course without at any time presenting any of the three symptoms of pain, tenderness and muscular rigidity. He illustrates this very forcibly by an excellent case report.

3. Tinker advances some excellent practical ideas in regard to surgery teaching. He advocates teaching antisepsis and arrest of hemorrhage practically in the laboratory and operating room, as well as didactically in the class room. Anesthesia also should be taught in this way. Practical and laboratory tests or examinations should be given when possible instead of written and oral examinations. Current literature can be used in some cases instead of exclusive textbook instruction. Surgical diagnosis should be given more attention than major operative surgery. [E. H. R.]

9. GROVE, W. G. *Acromegaly and Goiter. Report of a Case.*

1. Minor presents an interesting and fair discussion of the use of the x-ray in the diagnosis of pulmonary tuberculosis. He does not advise any physician to provide himself with such an apparatus unless he is willing to study it, become absolutely familiar with it and use it in every

case. He advises fluoroscopy rather than radiography. In early diagnosis this method must always be subservient to older methods of percussion, auscultation, etc. It is of great value, however, in giving exact information as to the location and extent of any given lesion. He discusses what it shows in moderately advanced and advanced cases, as well as in bronchial glands.

6. Meader concludes from his study of the bactericidal power of the blood serum of a typhoid carrier before and during a course of vaccines that (1) the bactericidal power of the blood serum of a typhoid carrier may be that of a normal person. (2) A carrier may be actively immunized to B. typhosus by the use of autogenous vaccines, and in so doing the bactericidal substances in the blood may be markedly increased. (3) A carrier, if vaccinated so as to bring about an increase of bactericidal substances, may cease to harbor bacilli. (4) The best therapeutic dose seems to be 75 to 400 million. The carrier on which he based this study ceased to harbor bacilli after vaccination. [J. B. H.]

2. Rogers describes a method of treating cholera by means of hypertonic saline injections given during the collapse stage, either subcutaneously or intravenously. Combined with this he gives various drugs to raise the blood pressure, usually digitalis, strophanthus, adrenalin, or pituitary extract. In addition to these methods of combating the toxemia he gives permanganates first in solution to drink in place of water, beginning with ½ to 1 gr. to the pint and increasing to 4 to 6 gr. to the pint. This he gives *ad libitum*. Calcium permanganate is the best for this purpose. Secondly, he gives potassium permanganate in a salol-coated 2-gr. pill every fifteen minutes for the first two hours, then every one-half hour for about twelve hours till the stools become green and less copious. By these methods the mortality was reduced from 59% to 34.7% by means of hypertonic salt solutions, and from 34.7% to 23.3% by means of permanganate during the last year.

17. Dawson reports some interesting cases of cutaneous diphtheria which occurs usually in children. It takes the form of an impetiginous eczema, nearly always on the head and face, and associated with a severe conjunctivitis after otorrhea and rhinitis. [J. B. H.]

14. CITRON, J., AND MUNK, F. *Cause of the Wassermann Reaction.* (*Reply to article in No. 38 on same subject.*)

3. These authors had the opportunity of studying two cases of congenital syphilis which had died two and four days after an injection of Ehrlich's new preparation. The tissue was stained by the Levaditi method, and a prolonged search was made throughout all the organs. In no organs were spirochete found except in the lungs, and here they showed marked signs of degeneration and agglutination. This was most marked in the case that received the smaller dose. The explanation of why they persisted in the lungs is not clear. They consider that these cases confirm the view that this compound is a specific poison for the spirochete.

4. From Werner's experiences with Ehrlich's new preparation it seems fair to conclude that it has a specific action upon the malarial parasite and that this is more marked against the tertian than the tropical form. He advises its use in all cases where the parasites resist quinine or the patient has an intolerance for quinine. [C. F., JR.]

10. STEINDORFF, K. *The Action of Atoxyl on the Eye.*

3. Cohn reaches the following conclusions in regard to the value of the Von Pirquet skin reaction. Its greatest worth is in the diagnosis and prognosis of tuberculosis in infants. A positive reaction in older children or grown persons he considers of no practical value, neither can a negative reaction absolutely rule out tuberculosis in the case of exhausted or emaciated patients. Positive diagnosis of infection with tuberculosis early in infancy demands a grave prognosis. Of 18 cases under one year of age, 16 died. [J. L. H.]

DEUTSCHES ARCHIV FÜR KLINISCHE MEDIZIN. BAND 100.

HEFT. 1–2. SEPT. 19, 1910.

1. *EDENS, E. *A Study of Pulse Tracings.*
2. *HANNES, B. *The Relation of Chromaffin Cells of the Suprarenals under the Influence of Experimental and Natural Diphtheria Infections.*
3. *HEDINGER, M. *The Value of Renal and Cardiac Medicines on Diseased Kidneys.*
4. SANDILOWSKY, I. *The Influence of Increased Temperature on Blood Concentration.*
5. FISCHLER, F. *The Occurrence of Acute Severe Liver Degeneration on Animals with Eck's Fistula with Complicating Pancreas Fat Necrosis, and also Some Remarks about the Relation between Liver and Pancreas.*
6. ROBINSON, G. C., AND DRAPER, G. *The Presphygmic Period of the Heart.*

9. BINGEL, A., AND CLAUS, R. *Further Investigation in the Blood-Pressure-Raising Substance of the Kidneys.*
10. JOLLES, A. *Method of Determining Iron in the Blood.*

1. Edens has reviewed the literature very carefully on the question of pulse tracings and gives a very good description of what points may be used in regard to diagnosing the pathologic condition of the heart from the tracings, and also what points may be brought out in regard to the heart function. A long list of references is included.

2. Hannes, from experimental work on guinea pigs with diphtheria toxin and the study of human cases of diphtheria, concludes that there is no relation between death in these cases and the chromaffin cells of the adrenals.

3. From experimental work Hedinger has learned that certain diuretics, such as digitalis, theophyllin, etc., act more effectively in the early stages of experimental nephritis caused by poisons which attack the tubules. In the later stages of these experimental nephritides they do not show an increased action. In any stage of the nephritis caused by drugs which affect the circulatory apparatus of the kidney they do not show an increased activity.

7. In infectious diseases and in the presence of toxins, the liver loses its tolerance for levulose and its content in glycogen. Simple increase of temperature, however, does not cause any diminution of the tolerance for levulose. Therefore these tests for disease of the liver are of no value in cases of acute infection with fever. These results are from a combined study of human cases and animal experiments. [C. F., JR.]

DIE THERAPIE DER GEGENWART.

JULY, 1910.

5. FRAENKEL, M. *The Importance of Roentgen Rays in Gynecology.*
6. **Berlin Medical Society, Session of June 22, 1910. Paul Ehrlich's Remedy for Syphilis.*

6. In April, 1910, Hata (Ehrlich's co-worker) made the first announcement of No. 606, dioxy-diamido-diarsenobenzol, a new preparation which had positively cured certain protozoan diseases in animals. Experimental syphilis in rabbits had been annihilated by it. Encouraged by these results, Ehrlich had given the remedy to Alt to try on paralytics and later to Schreiber to use on syphilitics. These clinical tests gave remarkably favorable results. In March, 1910, Ehrlich turned the remedy over to Wechselmann for tests on cases of lues in the Rudolph Virchow Hospital. Wechselmann now reports his first series of forty-eight cases. From the observations of these clinicians, which embrace some hundred cases, it is evident that in the doses used, "606" has no essential toxicity. In its curative effect it is far superior to anything hitherto used in fighting syphilis. All stages are affected. Whether the disease be hereditary or acquired, whether its manifestation be a chancre, a secondary roseola or a late visceral lesion, the effect of "606" is magical. The most wonderful thing about it is its action in cases which have obstinately resisted mercurials and other treatment. [L. D. C.]

6. KÖHLER, F. *Tuberculin Therapy.*

2. Tachau reports his experience and that of others with the intravenous use of antitoxin in diphtheria. This treatment has been tried out during the past ten years in Italy, France, England and more recently in Germany, where clinical observation has been corroborated by animal experimentation. The results have been the same everywhere. In ordinary cases there is more rapid disappearance of toxemia and less antitoxin is necessary than when given by the subcutaneous route. In very toxic cases and in cases with circulatory and renal complications it has no greater effect than when given subcutaneously. Untoward effects are more common. Chill, fever and collapse occur in many cases almost immediately after injection and pass off within a few hours. Collapse is alarming and demands vigorous stimulation; it is sometimes accompanied by a general erythema. Tachau sees in the intravenous use of antitoxin no essential therapeutic advantage over the subcutaneous method, and in consideration of its complex technic and its alarming untoward symptoms, he has discarded it. 5. FISCHER, W. *The Ehrlich Treatment of Syphilis.*

4. Meidner has used Ehrlich's "606" on all cases of syphilis entering the Moabit State Hospital, Berlin, since May 1, 1910. The luetic manifestations have been varied — syphiloderms, perforating ulcers, rectal stricture, gummata, ocular palsies, cerebral and spinal lues, post-syphilitic headache, tabes and dementia paralytica. He concludes from this clinical experience that amido-arsenobenzol is a remarkable remedy for syphilis of the skin and mucous membranes. In visceral lues it has cured in single dose more often than mercury and iodide over a long period. Of especial importance is its prompt action in desperate cases. Cicatricial changes are not attacked and damage to nerve tissue is not made good. Tabetics and paretics are not susceptible to this drug, although some relief of ataxia and ocular palsies has been noted. "606" is superior to mercury and iodide in that the treatment is very short and the effect very prompt. Whether because of this advantage dioxy-diamido-diarsenobenzol will ever supplant these older specifics depends on whether it kills the spirochete for all time. This point can be determined only after years of observation. [L. D. C.]

Obituary.

GUSTAVUS LINCOLN SIMMONS, M.D.

DR. GUSTAVUS LINCOLN SIMMONS died at Sacramento, Cal., Oct. 4, 1910, aged seventy-eight years six months. He was born in Hingham, Mass., in 1832, and was one of the pioneers in California, rounding the "Horn" in 1849. He returned to Boston and took up the study of medicine at Harvard, where he graduated in 1856, since which time he has been in active practice in Sacramento until within two months of his death.

At various times he has held the following positions: President California State Medical Society; county physician; surgeon National Guard of California; and for over twenty years was commissioner in lunacy. He was the first in California to successfully perform ovariotomy and the wiring of tendons.

Dr. Simmons exhibited in an enviable way in his life and work a happy combination of the virtues and merits generally regarded as characteristic of the Atlantic and Pacific coasts of our country.

He is survived by a widow and three children, a daughter and two sons: Dr. Gustavus C. Simmons, Harvard 1885, and Dr. Samuel Ewer Simmons, Harvard 1899.

LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND OTHER OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED OCT. 19, 1910.

GASSAWAY, JAMES M., surgeon. Granted one month's leave of absence from Oct. 7, 1910, on account of sickness.

SPRAGUE, E. K., surgeon. Granted fifteen days' leave of absence from Oct. 28, 1910.

MATHEWSON, H. S., passed assistant surgeon. Granted one day's leave of absence, Oct. 12, 1910, under paragraph 189, Service Regulations.

GOLDBERGER, JOSEPH, passed assistant surgeon. Granted four days' leave of absence from Oct. 26, 1910.

MCLAUGHLIN, A. J., passed assistant surgeon. Directed to report at the Bureau upon special temporary duty. Oct. 17, 1910.

BOGGESS, J. S., passed assistant surgeon. Granted one month's leave of absence from Nov. 14, 1910.

RUCKER, W. C., passed assistant surgeon. Directed to proceed to New York, N. Y., upon special temporary duty. Oct. 12, 1910.

DE VALIN, HUGH, passed assistant surgeon. Granted thirty days' leave of absence from Nov. 2, 1910.

DUFFY, B. J., assistant surgeon. Relieved from duty at Buffalo, N. Y., and directed to proceed to Tompkinsville, N. Y., and report to the commanding officer of the Revenue Cutter "Seneca" for duty. Oct. 12, 1910.

JACKSON, JAMES M., Jr., acting assistant surgeon. Granted thirty days' leave of absence from Nov. 1, 1910.

TAPPAN, J. W., acting assistant surgeon. Leave of absence for twenty days from Oct. 1, 1910, amended to read twenty days from Oct. 5, 1910.

TERRY, M. C., acting assistant surgeon. Granted thirty days' leave of absence from Nov. 1, 1910.

BECK, J. E., pharmacist. Granted seven months' leave of absence without pay from Oct. 20, 1910.

BOARD CONVENED.

Board of medical officers convened to meet at the Bureau Oct. 20, 1910, for the purpose of conducting a physical examination of an officer of the Revenue-Cutter Service. Detail for the board: Assistant Surgeon-General J. D. Long, chairman; Assistant Surgeon Paul Preble, recorder. Oct. 19, 1910.

CHANGES IN THE MEDICAL CORPS U. S. NAVY DURING THE WEEK ENDING OCT. 29, 1910.

BROWNELL, C. D., surgeon. Detached from the "North Dakota" and ordered home to wait orders. Oct. 21.

PLEADWELL, F. L., surgeon. Detached from the bureau of medicine and surgery, Navy Department, and ordered to the "North Dakota." Oct. 21.

SHOOK, F. M., passed assistant surgeon. Granted sick leave for one month when discharged from treatment at the Naval Medical School Hospital, Washington, D. C. Oct. 24.

MCDOWELL, R. W., assistant surgeon. Granted sick leave for two months when discharged from treatment at the Naval Medical School Hospital, Washington, D. C. Oct. 24.

CATHER, D. C., passed assistant surgeon. Detached from the "Iowa" and ordered to the "Delaware." Oct. 25.

WHITMORE, G. B., assistant surgeon. Detached from the "Delaware" and ordered to the "Connecticut." Oct. 25.

MCDOWELL, R. W., assistant surgeon. Detached from the "Connecticut." Oct. 25.

BROWNELL, C. D., surgeon. Ordered to duty at the Naval Hospital, Las Animas, Colo. Oct. 26.

KELLEY, H. L., passed assistant surgeon. Commissioned passed assistant surgeon from June 6, 1910. Oct. 26.

LAWRENCE, H. F., passed assistant surgeon. Commissioned passed assistant surgeon from Sept. 21, 1910. Oct. 26.

SOCIETY NOTICE.

NEW YORK STATE DEPARTMENT OF HEALTH. — The tenth annual conference of the sanitary officers of the state of New York will be be held in the Y. M. C. A. Auditorium, Buffalo, Wednesday, Thursday and Friday, Nov. 16, 17, 18, 1910.

RECENT DEATHS.

DR. JOHN E. ALLEN, of New York, died from Bright's disease on Oct. 25. He was graduated from Bellevue Hospital Medical College in 1875, and for twenty-five years was connected with the New York City Department of Health.

DR. LENOX GRESHAM WALLING, who died of nephritis on Oct. 24, at Harrisville, R. I., was born there on June 19, 1881. He graduated from Brown University in 1902, and subsequently studied at Columbia Medical College. From 1906 to 1908 he served as house-officer at the Rhode Island General Hospital and at the Providence Lying-in Hospital. For the past two years he had been in practise at Providence.

DR. FREDERICK HOLME WIGGIN, of New York, died at Atlantic City, N. J., on Oct. 28. He was born at Kingston-on-Thames, England, in 1853. After being graduated from the Rensselaer Polytechnic Institute, Troy, and the University of the City of New York, he received the degree of M.D. from Bellevue Hospital Medical College in 1877. He served as interne at Bellevue Hospital and then practised at Litchfield, Conn., until 1890, when he removed to New York. Last year he retired from practise on account of ill-health. Among the honorary positions held by Dr. Wiggin are those of president of the New York County and State Medical Associations and president of the Alumni Society of Bellevue Hospital. During 1897 and 1898 he was adjunct visiting surgeon to Bellevue Hospital, and at the time of his retirement was gynecologist to St. Elizabeth's Hospital and consulting surgeon to the City, the Metropolitan Throat, and the Litchfield County hospitals.

SPINAL ANESTHESIA.

BY FREEMAN ALLEN, M.D.,

Consulting Anesthetist, Massachusetts General Hospital and to the Children's Hospital, Boston.

THE early workers in spinal anesthesia, chief among whom were Bier, of Berlin, and Tuffier, of Paris, reported frequent untoward effects both during and after operation, and a considerable mortality. This was in the days when cocaine was used, and before the importance of adrenalin was recognized. Since 1899, when Bier's first work appeared, cocaine has gradually given way to the less toxic and equally efficient stovaine, novocain or tropacocaine, and is now never used. Also the importance of mixing adrenalin with any solution to be injected into the spinal canal has been recognized.

The result is that spinal anesthesia can no longer be considered dangerous, but is now relatively safe and has a distinct place in surgery.

On Nov. 9, 1909, at the Massachusetts General Hospital, we began a series of spinal anesthesia cases which now amounts to 117 cases. These combined with 34 cases done by the writer outside of the hospital make a series of 151 cases.

INDICATIONS FOR SPINAL ANESTHESIA.

Alcoholism, old age, debility, certain cardiac cases, bronchitis, arteriosclerosis, extreme dread of general anesthesia, diabetes, urinary septicemia, shock, intestinal obstruction, renal insufficiency.

These are some of the conditions which singly or in combination have been our indications for doing spinal anesthesia. With very few exceptions there has been a clear indication in all of our cases.

In the course of the work, however, we have come to distinguish certain classes of cases in which spinal anesthesia works so well as to be the anesthetic of election whether a definite indication is present or not. These are simple herniotomy in men, prostatectomy, hemorrhoids, fistula in ano, amputations of leg or thigh, cystoscopy and urethral or bladder operations.

Of the 151 patients, only 14 were women. There were no children.

Of the 14 women, several asked to have spinal anesthesia on account of dread of ether. The same is true of the men, who in many instances were delighted with it and recommended it to their fellow patients.

Besides the above-mentioned operations, 3 cases of appendectomy were done.

In one railroad accident case both thighs were amputated under spinal anesthesia. It is highly probable that in this case general anesthesia would have been fatal. The patient survived and is now well.

The results of spinal anesthesia in prostatectomy are remarkably satisfactory.

PREPARATION OF PATIENTS FOR SPINAL ANESTHESIA.

There need be no special change from the routine preparation of patients for general anesthesia. It is, however, important to feed and if necessary stimulate patients just before spinal anesthesia. They should at all events never be brought to operation starved. They should be given a light breakfast the morning of operation and an eggnog just before operation. The rectum must be emptied, as under spinal anesthesia the sphincter ani is completely paralyzed.

Rather large doses of morphine (gr. ¼) should be given twenty minutes or half an hour before spinal anesthesia, especially if the operation is to be a long one.

TREATMENT OF PATIENTS DURING AND AFTER OPERATION.

The psychic element is of great importance in spinal anesthesia, and the patient's "morale" must be handled with care. The choice between general and spinal anesthesia should not be "put up to" the patient. The surgeons should decide whether or not the case is one for spinal anesthesia. If it is, the advantages of this method over general anesthesia should be explained to the patient.

Spinal anesthesia, although a routine in many European clinics, is still new in America. The result is that surgeons and attendants unfamiliar with the method are apt to make too much of it and unwittingly make their patients feel that something very extraordinary is going to be done. This is bad for the patient's courage.

When puncture is being done, as few people as possible should be present. After puncture has been done it is better not to question the patient at all as to his sensations or lack of them. If patients feel ill or are in pain they will always say so promptly. Persistent questioning as to whether a patient feels pain or not does no good and may easily make him imagine he does feel pain. Therefore, we test the anesthesia not verbally, but with a pin concealed from the patient, relying upon reflex movement for a guide. If the anesthesia seems satisfactory when tested by a pin-prick, the incision should be boldly made without telling the patient and without questioning him in any way. If left alone, a patient will often express surprise to hear that the operation is begun when it is more than half finished.

It is important to screen the field of operation from the patient. This may be done by a screen with which many operating tables are fitted, or by placing a towel over the patient's eyes. We have seen perfectly anesthetized patients lose their "nerve" entirely on catching sight of the wound.

It is a good plan to have a sympathetic nurse or attendant act as "mental anesthetist" by conversing with the patient during operation.

SOLUTIONS USED.

Cocaine has now no place in spinal anesthesia. We use stovaine, novocaine or tropacocaine, always in combination with adrenalin. Freshly prepared solutions have not given satisfaction. The solutions used must not be subjected to the degree of heat necessary to sterilize them, as this spoils their efficiency. They also become in-

efficient if exposed to alkalies. Therefore, the syringe must not be boiled in water containing soda, and the ampoules containing the solution must be made of alkali-free glass. Proprietary preparations give the best satisfaction. They come in hermetically sealed ampoules which must be filed open. We use:

(1) Stovaine-Billon (Poulenc Frères, Paris; Parmele Pharmacal Company, New York). This is dispensed in ampoules of 2 ccm. each. Each cubic centimeter contains adrenalin-borate, 0.00013; stovaine, 0.04; chloride of sodium, 0.0011.

The average dose of stovaine is 4 cgm. These ampoules contain 8 cgm. and are, therefore, double dosed, enabling us to give a minimum or maximum dose. We never use more than 6 cgm.

(2) Novocain, 5% solution (Meister Lucius Bruning, Hoechstadt am Main, Germany).

Ampoules of 3 ccm. containing novocain, 0.15; adrenalin borate, 0.000325; 5 drops of 1:1000 boric solution. Dose, 2–3 ccm. (10 or 15 cgm. novocain). Usual dose, 2.5 ccm.

(3) Tropacocaine as used by Bier. He uses at present only tropacocaine. Ampoules contain 1.3 ccm. of 5% solution tropacocaine, plus adrenalin hydrochloride 0.00013 per cubic centimeter. The dose of tropacocaine is thus 5 cgm.

In the series of 151 cases stovaine has been used 88 times; novocain, 36 times; tropacocaine, 27 times.

Stovaine gives a more intense and longer anesthesia with a smaller dose than the others, but must be used with great caution. Novocain requires a larger dose than stovaine to produce the same effects and is less toxic. Tropacocaine is the safest of the three and is used entirely by Bier, but it does not produce as lasting an anesthesia as the others.

The duration of anesthesia varies with the drug and its dose. It is usually from forty-five minutes to two and a half or three hours. A dose of tropacocaine (5 cgm.) often lasts only forty-five minutes, but may last an hour and a quarter. A dose of novocain (10 cgm.) will often last two hours and sometimes longer. A dose of stovaine (4 or 5 cgm.) will last two hours or more.

By increasing these doses an anesthesia of three hours can be obtained. No operation requiring so long a time as that should be done under spinal anesthesia, as the patient's nerves will not ordinarily stand it.

INSTRUMENTS.

We use syringes and trochars made by Georg Haertel, of Breslau, and exactly similar to those used by Professor Bier. The syringes made especially for spinal anesthesia have not stood repeated boiling, so we have substituted the 5 or 10 ccm. German "Record" syringes. These have graduated glass barrels, metal pistons and metal points, and stand boiling well. Of course the piston must be out of the barrel when boiled owing to the uneven expansion of glass and metal. The trochars are made of nickel and, being pliable, cannot break off in the tissues or if struck against bone. They are 10 cm. long with a diameter of 0.8 mm. They have a short excavated bevel and are fitted with mandrins. The short bevel is necessary to insure the whole of the lumen being in the canal at the time of puncture.

In Germany, where many spinal punctures are made in succession, the syringe and trochars are left always ready in a thermochest so that when in use they are at about body temperature. The thermo-chest is not necessary when only one puncture is done at a time. The syringe should, however, be hot when used as this warms the solution to be injected, making it approximately body temperature and thus much better tolerated by the patient. A small file such as is provided by the makers of Stovaine-Billon should be boiled with the syringe and used to file open the ampoules of the solution.

TECHNIC.

Position. — In very sick patients it may be necessary to make the puncture with the patient in the recumbent posture. It is objectionable, however, because it is more apt to result in unilateral anesthesia. If it must be done, the patient should lie square on his side with the knees drawn up, the forearms flattened on the chest, the head flexed and the whole back arched as much as possible.

It is much better, however, to have the patient *sitting* squarely on the table with his feet hanging over the side, the arms folded across the abdomen, the head flexed on the chest and the back bowed as much as possible toward the operator. The skin for a circle of six inches about the point of puncture should then be cleaned by shaving if necessary, soap and water, antiseptic alcohol, and ether.

The edge of a sterile towel should then be stretched across the spine in such a way as to connect the two highest points of the iliac crests. The towel's edge should then cross the body of the fourth lumbar vertebra, which can be palpated, and from this the first or second lumbar interspace located. Puncture may be made in any lumbar interspace, but generally the second or third is the best. The cord ends opposite the body of the second lumbar vertebra.

Having located the interspace, the skin over it should be marked by some blunt instrument or by the finger nail. The boiled syringe and trochar, together with the ampoule of anesthetic solution, must be at hand on a sterile table. The syringe is put together, the ampoule opened and the solution drawn into the syringe through the trochar and accurately measured. The mandrin is replaced in the trochar, which is then wiped dry with a sterile sponge.

An assistant then thoroughly freezes the skin over the marked space with ethyl chloride.

Puncture is made in the median line or a little to one side of it. The first step is to quickly pierce the skin and subcutaneous tissue, and then stop. Then the mandrin is withdrawn from the trochar, which is pushed carefully forward, possibly slightly upward, in the median line. As soon as

the dura is pierced there will be a flow of spinal fluid from the trochar.

The fluid should flow either in a rapid succession of large drops or in a steady stream. If it does not flow in this manner, injection should not be made, but the trochar moved to and fro or cleared by reinserting the mandrin until a suitable flow of fluid is obtained. This is of the greatest importance, and neglect of it is one of the commonest causes of failure.

When a few drops have escaped from the trochar the syringe containing the solution is attached and the piston gently withdrawn until a suitable amount of spinal fluid has been allowed to mix with the anesthetic solution. The amount of fluid thus withdrawn varies from 2 to 10 ccm. Usually 4 or 5 ccm. suffice.

The mixed fluids are then gently injected, the syringe detached, the trochar withdrawn, the puncture covered with a sterile towel or dressing and the patient placed recumbent with the head well supported.

Professor Bier regulates the height of the anesthesia by the force of injection, amount of spinal fluid used to dilute the anesthetic and by the use of the Trendelenburg posture. If his technic is regidly adhered to and only tropacocaine used, this may produce good results; but the Trendelenburg posture has so often been followed by untoward symptoms during operation that we have given it up and rely more on the force of injection for obtaining a high anesthesia.

Failures to produce anesthesia are most often due to faulty technic or inefficient solutions; and less often to anatomical causes, such as obesity or osteo-arthritis of the spine.

In the series of 151 cases there have been 7 failures. Three of these were early cases and were due to inefficient solutions. These solutions were freshly prepared and spoiled by overheating.

In two cases probably due to osteo-arthritis of the spine the vertebral interspaces could not be palpated and puncture seemed impossible. These were, however, early cases and among the later cases several patients with osteo-arthritis of the spine were successfully punctured, although sometimes five or six attempts were necessary.

In one case obesity was so great that no vertebral interspaces could be palpated and after two attempts it was given up. This was also an early case and several cases of obesity have been successfully punctured since.

The following is an example of failure due to error in technic. In a middle-aged man puncture was made in the second lumbar interspace. Spinal fluid flowed in very slow drops, and moving the trochar produced no better flow. The operator being hurried, injection was made when only a few drops of spinal fluid had been withdrawn to dilute the anesthetic solution. The result was total failure. In such a case another puncture should be made in a different interspace.

UNTOWARD EFFECTS DURING OPERATION.

The commonest untoward effects that occur during operation are nausea and vomiting, faintness, air-hunger, pallor, sweating and restlessness. These are all toxic symptoms and are due to too great an upward diffusion of the anesthetic drug in the spinal canal. The commonest cause of this is the use of the Trendelenburg posture or too forcible an injection in an effort to obtain a high anesthesia. Too large a dose will also cause them. They can easily be avoided by caution in these matters.

Nausea and vomiting occurred during operation in nine of our cases. It was always transient and subsided promptly with treatment. If taken in time these symptoms may be checked in some patients by giving a stiff drink of whiskey or brandy. If this fails the head and shoulders should be raised and a small dose of strychnine given hypodermically. Facial massage and lip-friction by the repeated application of hot towels acts very well.

After operation the patient should be placed in bed with the head and shoulders raised. Feeding and stimulation may be begun at once by mouth. Nothing given by rectum will be retained until the anesthesia has entirely passed away. Special precautions against hot-water bottle burns are necessary.

AFTER-EFFECTS.

The commonest immediate after-effects of spinal anesthesia are headache, backache, stiff neck, sciatic pains, paralyses, ocular palsies. Our cases have been remarkably free from after-effects. Only two of our cases have had headache. In both cases it was very severe occipital and frontal headache and resisted treatment by ordinary headache remedies. In one case it lasted over twenty-four hours.

One patient, a doctor, complained of sciatic pain which he likened to "growing pains." This pain was very severe and required morphine to control it. It lasted eighteen hours.

There were a few cases of transient stiff neck.

Case.

One case, the first done outside the hospital, was striking as illustrating effects during and after operation that may or may not be due to spinal anesthesia. The patient was a heavily built man of fifty-five years, with mitral disease, slight arteriosclerosis, very deaf. He gave a history of two previous attacks of numbness of the left arm and hand. The patient required operation for double inguinal hernia. He was given ¼ gr. of morphine twenty minutes before operation.

One and one-half cubic centimeters of Stovaine Billon (6 cgm. stovaine) diluted with 3 ccm. of spinal fluid was injected in the second lumbar interspace. The injection was fairly forcible and the patient placed in rather marked Trendelenburg for three minutes. The table was then placed level and the patient cleaned for operation. In about five minutes he complained of faintness and showed marked pallor, sweating, air-hunger, nausea, retching and vomiting. Brandy by mouth produced no improvement. The operation was

begun and the anesthesia proved to be perfect. Soon after the beginning of the operation the patient lost consciousness and the respiration became Cheyne-Stokes in character. Massage of the face and lips with hot water produced slight improvement. The pulse improved after a hypodermic of strychnine. Patient remained unconscious throughout the operation and for two hours after being put to bed. On being put to bed distinct and complete left hemiplegia was observed. This cleared up in less than twenty-four hours, but left slight paralysis of the left wrist which persisted two days longer.

During the next twenty-four hours there developed complete paralysis of the right leg. This persisted for three weeks. It then gradually cleared up and in two months was entirely well.

In view of the patient's two previous attacks of apparent left hemiplegia it does not seem certain that this was altogether due to spinal anesthesia.

The above case was undoubtedly alarming, but the majority of the cases were strikingly favorable and convince the writer that spinal anesthesia has a distinct and useful place in surgery.

The writer wishes to thank the members of the Surgical Staff and the House Pupils of the Massachusetts General Hospital for encouragement and assistance.

ETIOLOGY OF ELEPHANTIASIS.*

BY GEORGE CHEEVER SHATTUCK, M.D., BOSTON,

Assistant Physician to Out-patients, Massachusetts General Hospital; Physician to the Harvard Clinic.

HAVING recently become interested in sporadic elephantiasis through seeing a few cases, I undertook by a review of the literature to ascertain the present state of knowledge of this disease. Although much has been written about it, important questions of etiology remain obscure. Firstly, there are several types of elephantiasis, and several allied or similar conditions which merge with it in such a way as to render sharp distinctions impossible. Moreover, cases pathologically typical show striking differences in clinical history and in apparent etiology.

The term elephantiasis, as you know, formerly had a wide application. There was E. graecorum, now called leprosy, and E. arabum which included all other forms. Virchow regarded Madura-foot as a form of elephantiasis and was in doubt whether or not to include also fibroma molluscum. After this the application of the term became progressively narrower until a relation had been established between elephantiasis and filariasis. A tendency was then shown to regard the tropical cases as true elephantiasis and to speak of sporadic forms as pseudo (Brault) or false elephantiasis. This tendency met so much opposition from Hutchinson and others that sporadic and endemic cases are now included alike within the current meaning of the word.

There are several important varieties. One of the congenital forms involves the whole body. It occurs generally in acephalic monsters, and is due probably to congenital defect of the lymphatic system (Virchow). Elephantiasis lymphangiectodes and E. telangiectodes (Esmarch and Kuhlenkampff) resemble angiomata, are probably congenital and seem more closely related to tumors than to acquired elephantiasis. There is a similar cystic form (Virchow), a fibromatous form related to fibroma molluscum (Esmarch and Kuhlenkampff), and a neuromatous variety, but type cases of these have little in common with ordinary elephantiasis.

As this paper deals only with lymphatic elephantiasis, these forms need no further mention here.

Elephantiasis is again divided into groups corresponding roughly to etiology, — the congenital, the sporadic, and the endemic, — but until important questions of etiology have been settled, no classification on this basis can be satisfactory. The congenital cases present great variety. A few of them resemble so closely the common acquired forms as to suggest a similar etiology; but other cases are quite different, and so little is really known that I prefer to leave congenital elephantiasis out of this discussion.

Acquired cases of lymphatic elephantiasis are divided for descriptive purposes into elephantiasis of the legs, of the genitals, of the face and of the scalp. The older writers gave separate names to cases differing in external appearance or consistency. They distinguished thus, E. glabra, E. verrucosa, E. ulcerosa, E. mollis and E. dura. These distinctions do not correspond to essential differences.

Elephantiasis in the broader sense is not a distinct disease but a group of pathological conditions which leads to progressive enlargement of the part affected. How far this is true of acquired lymphatic elephantiasis is an important question. Undoubtedly, acquired elephantiasis is much the same in its clinical manifestations and in its pathology whether it appears endemically or sporadically.

The character common to typical cases of lymphatic elephantiasis is progressive enlargement. This enlargement is due to chronic edema, hyperplasia of connective tissue and dilatation of lymphatic vessels. The *central question* in the etiology of elephantiasis is as to the *relation between edema, hyperplasia* of connective tissue and *lymphatic dilatation*. To answer this question it is necessary to study independently the causes which may lead to each of these conditions.

Edema may be traceable to local or to distant causes of venous stasis; for example, to phlebitis; to chronic cardiac or renal disease; to disturbances of innervation, peripheral (Obersteiner and Redlich), or central (Edinger), as in polyneuritis or syringomyelia; to abnormal blood, as in anemia; to cachexia; or to inflammation. Experiments of Ranvier show that ligation of the femoral vein in a dog is not followed by edema unless the sympathetic fibers to the leg have been cut. Cutting the sympathetic causes arterial

* Read before the American Society of Tropical Medicine, June 11, 1910, St. Louis, Mo.

dilatation and increase of local intravascular pressure. Cornil and Ranvier believed this to be the real cause of edema, excepting perhaps the edema of cachexia. They say that if tension is sufficient, edema will occur even without obstruction of veins. They attribute the edema of inflammation to the same cause. Guyot [1] suggested trophoneurosis and Cornil,[1] interstitial neuritis as possible causes for the edema of elephantiasis. P. zur Nieden [2] believed that edema in elephantiasis was due to mechanical obstruction of lymphatic circulation, resulting from inflammation, and Lallement [3] attributed it to atony of vessel walls.

Abundant clinical evidence shows that obstruction of lymphatics does not often produce manifest stasis of lymph, and Cohnheim's [4] experiments indicate that lymph stasis cannot produce *edema* if lymph formation is normal and if the veins are patent.

Therefore, the edema of elephantiasis is rarely if ever due to obstruction of lymphatics solely, but lymphatic changes may act as contributive causes of edema. It is important to recognize that venous thrombosis is commonly present in lymphatic elephantiasis, that proliferation of endothelium in the capillaries is one of the earliest changes (Winiwarter), and that this change favors obstruction. Edema in elephantiasis is influenced also by gravity. It begins generally in the legs and extends upward. In the earlier stages the edema is diminished by rest in bed and increased by walking.

Observation shows that chronic edema from almost any cause may form the basis for subsequent elephantiasis and that persistent edema is its first visible manifestation. In the majority of chronic edema, however, no elephantiasis follows. Kaposi says that edema with lymph-stasis is more likely to result in elephantiasis than is pure serous edema. From histological studies, Wernher concludes that the edema of elephantiasis begins in the skin.

We come now to the causes of varicosity and thickening of lymphatics, dilatation of lymph spaces and stasis of lymph. Virchow says that, in elephantiasis, obstruction and dilatation of lymph channels occurs early and that sometimes only the small, sometimes only the large, ones are affected. It has been observed earliest in the papillary layer of the skin (Winiwarter) and where the network of lymph capillaries is most extensive (Busey). When lymph channels are dilated, we may assume that there is some degree of lymphatic stasis, whether edema be present or absent, but experiments show that obstruction of large trunks, even ligation of the thoracic duct, does not always cause ectasis (Magendie, Dupuytren, Lesser [5]). Why changes in the walls of lymphatic vessels do not always follow retardation of lymph-circulation is explained by the rich anastomosis and the low pressure in the vessels. This is true especially of the smaller lymphatics (Fischer). Unna believes that lymph stasis can be produced only by hindrance to the escape of blood from the veins and that lymph stasis can under no circumstances produce extensive lymphangiectasis. He quotes various experiments to prove this. Moreover, ectasis occurs so frequently without obstruction of lymphatics that other explanations for it are needed. The following theories have been offered: that ectasis may result sometimes from proliferation (Langhans, Torock, Nasse [5]), that atony may cause it (Corre [6]), that congenital weakness or anomalies may predispose to it (Busey, Fischer), that gravity may be the chief factor (Wernher [7]), and that chronic heart disease with resulting venous and lymphatic stasis may produce it (Weigert [8]).

Busey shows in his monograph that the etiology of lymphangiectasis and of obstruction of lymphatics is multiple, and that to account for it in some cases, a congenital change or an inherited weakness must be assumed. Fischer says that, owing to the disagreement of pathologists, no satisfactory conclusions concerning it can be reached. He himself believes that proliferation of lymphatic vessels is an important factor, but he agrees with the majority that lymphatic varices may result when, in a limited area, most of the lymph vessels are obstructed, and he explains that, by overfilling, the elasticity of the vessels is impaired, and that insufficiency of valves may result either from dilatation or from destructive inflammation. He compares the production of lymphatic varices to that of venous varices. It is generally agreed that the filaria can produce varices in the lymphatics, but the way in which it does this is purely conjectural. Winiwarter believes that ectasis of small lymph-spaces is the *first* change in elephantiasis.

Briefly, we have reason to believe that stasis of lymph may sometimes be promoted if not actually caused by obstruction or destruction of lymphatic trunks or glands, by agents acting from within or from without, by proliferation of the smaller lymphatics, by changes in the walls of the lymphatic vessels due to inflammation, or by widespread destruction or thrombosis of small lymphatic vessels. These conditions may be either acquired or in part at least congenital.

Clinical observation teaches that lymph stasis, or a probable cause for such, is often a demonstrable antecedent to elephantiasis. If not a forerunner, it appears in the early stages of the disease. Busey is justified in the conclusion that *lymph stasis is a necessary factor in elephantiasis*, but that the *mode of its production is not essential*.

The third process which always accompanies elephantiasis is hyperplasia. Winiwarter says that it takes place in the endothelium of capillaries in tissue that appears normal near the margin of elephantiasis. A definite increase of vessels has been observed (Welt, Langhans, Rindfleisch [9]). In the early stage round-cell infiltration is found along the veins, but not around the lymph-vessels.

Dilatation of superficial lymph-capillaries and spaces is accompanied by proliferation of endothelium which leads gradually to obliteration of the deeper vessels. Capillaries, arteries and lymph vessels of the skin contain clumps of endothelial cells and coagulated fibrin, the nerve sheaths show increase of fibrous tissue, and inflammatory hyperplasia occurs in the glands (Cornil). Connective tissue hyperplasia is first apparent in the deeper layers of the skin. It penetrates thence into the subcutaneous tissue, especially along nerves and vessels, leads to atrophy of fat and muscle, and in extreme cases replaces them entirely. When the periosteum is attacked, the bones hypertrophy. In the earlier stages of elephantiasis all components of the skin except the elastic tissue may hypertrophy, but with further increase of connective tissue the other structures atrophy (Jarisch). Enormous increase of smooth muscle has been observed in the scrotum (Rindfleisch [9]), but the changes here are the same in general as those of elephantiasis of the legs. Virchow likens the cut surface in E. dura to bacon, says that it resembles a mass of scar tissue and that the essential change is progressive increase of connective tissue.

How can this proliferation be explained? Andral looked upon it as a "scirrhous degeneration." Virchow believed that an "irritative" condition exists from the first and that, in cases following venous obstruction, slight injury leads to inflammation. Wernher explained that chronic irritation results from decomposition of stagnant lymph, that this irritation leads to increased growth from the abundant building material, that "subinflammation," and finally inflammation, follows. Kaposi thought that stagnating lymphatic edema renewed by attacks of inflammation was the basis of connective tissue hypertrophy, and to lymphatic and inflammatory edema he attributed a high nutritive value. He could not explain why serous edema without inflammation is sometimes followed by elephantiasis. Inflammatory edema is characterized by a network of fibrin not seen in simple edema (Cornil and Ranvier). Busey and Jarisch accept the theory of increased nutrition through stasis, especially lymph stasis, and Kock [10] attributes hyperplasia to stasis combined with inflammation as in chronic suppuration, ulceration or eczema. It was pointed out by Winiwarter that elephantiasis is most apt to occur when repeated and long-standing arterial hyperemia has coexisted with impeded outflow of venous blood and of lymph. He attributed this hypertrophy to overnourishment, and considered stasis to be the most important predisposing factor. The stasis might be produced by any sort of mechanical obstruction or by chronic inflammatory hyperemia.[11]

These views were generally accepted until Bard [12] asserted that chronic edema *per se* could not cause a permanent increase of connective tissue. He attributed the sclerosis to inflammation, and advanced the theory that chronic thickening of cardiac valves, and sclerosis of the liver and kidneys, so often occurring with it, were all inflammatory and due to the same underlying cause; and that elephantiasis was a similar process.

After the advent of bacteriology Achalme [13] attempted to explain the supposed chronic inflammation by maintaining that the streptococcus could remain latent in the tissues and be responsible also for the attacks of acute inflammation. Guillet and others [13] tested this theory by attempting to cultivate bacteria from lymph withdrawn in the absence of demonstrable inflammation, and by searching for bacteria in sections of tissue from elephantiasis. Their results were uniformly negative. In the presence of acute inflammation the streptococcus has been isolated from a great many cases of elephantiasis, and Prout has asserted that elephantiasis, whether sporadic or endemic, is due to streptococcus infection. The majority of recent writers recognize that the streptococcus plays an important part in the etiology of many cases of *sporadic* elephantiasis; but they follow Manson in believing that the filaria is the principal factor in *tropical* elephantiasis. Dufougeré, who spent five years in the Antilles, believed at first that all elephantiasis was due to streptococcus lymphangitis. While there he saw many patients who had had repeated attacks of lymphangitis, but the majority of them did not develop elephantiasis. Nevertheless, every one of his 62 cases of elephantiasis affirmed that the trouble began with lymphangitis. Dufougeré isolated a peculiar diplococcus from 9 cases, and attributed elephantiasis to that rather than to the streptococcus. At about the same time Le Dantec [14] isolated a similar diplococcus, but he considered the presence of filaria necessary for the production of elephantiasis and explained the later disappearance of the filaria as due to inflammation produced by the diplococcus. Various other organisms have been cultivated in a few instances (Renon, Sabourand, Brault).

Less than a year ago Dubruel published some very important work on elephantiasis. His observations extended over five years, and for three years he was in Tahiti or neighboring islands. In this region elephantiasis is common, but other manifestations of filariasis, such as chyluria and varicose groin glands, are rare. Specimens of blood taken in the evening from 200 cases, about one eighth of the total population in the island of Moorea, were negative, although elephantiasis occurs there in about one twelfth of the population. No case of chyluria was seen, and no filaria was found by examination of centrifugalized lymph from cases of elephatiasis which had been operated on. The filaria was observed only in a single case which had been sent to the hospital with the diagnosis of typhoid fever.

Blood withdrawn in the absence of fever from outside the diseased area in cases of elephantiasis gave no growth on ordinary media, but at the

[14] Quoted by Dufougeré.

height of an attack of lymphangitis, blood from any part of the body yielded staphylococci in pure culture. Fluid taken from old cases that had not had acute inflammation for years generally gave no growth. Fluid withdrawn in the presence of lymphangitis showed streptococci more frequently than that withdrawn between attacks. Sometimes the fluid showed also staphylococci, but they were not infrequently mixed with other organisms. Two kinds of bacilli and a diplococcus are mentioned.

Important evidence points to the possibility of contagion in elephantiasis.

Dubruel's conclusions are as follows: That it does not appear that the filaria plays the part in elephantiasis attributed to it by Manson; that tropical elephantiasis should be brought closer to elephantiasis nostras, a bacterial disease following repeated erysipelas, and that during acute attacks of lymphangitis patients should be regarded as infectious and should not be admitted into open surgical wards.

From regions where the filaria and its intermediate host abound, Manson presents evidence proving that the filaria is an important factor in the production of elephantiasis. That it can cause dilatation and varicosity of lymphatics is probable. That it can of itself produce inflammation or fever is not proven. Manson says that, by injuring the lymphatics, the filaria predisposes to bacterial infection and that to infection the lymphangitis and fever are due.

It is undeniable, at any rate, that inflammation of bacterial origin often precedes, and generally accompanies, the development of elephantiasis wherever found. Doubtless in many cases inflammation plays an essential part in causing hyperplasia of connective tissue. The view that hyperplasia in elephantiasis may sometimes result from chronic non-bacterial irritation, or from hypernutrition in the absence of inflammation, is questionable, but many cases in which bacterial inflammation was never manifest can be cited in its favor. To explain this group of cases, and those in which elephantiasis develops after a single inflammatory attack, congenital anomalies or weakness of lymphatics may be inferred. On the other hand, it has been suggested that the congenital cases which resemble acquired elephantiasis may be due ultimately to intra-uterine infection.

SUMMARY.

1. The essential characteristics of typical acquired elephantiasis are lymphangiectasis, hyperplasia of connective tissue, and chronic edema.

2. The relation of these to each other in the production of elephantiasis is not clear.

3. It appears that these changes may frequently be attributed to the interaction of stasis and of inflammation.

4. Stasis always occurs early and persists.

5. Inflammation may precede or follow stasis, or may not be manifest at any stage of the disease.

6. Inflammation when present may be acute or chronic; and is generally traceable to bacterial infection.

7. Either chronic stasis or inflammation from any cause may predispose to elephantiasis, but even when they occur together, elephantiasis does not always result.

8. There is reason to suppose that congenital weakness or anomalies of lymphatics may play an essential part in the production of some cases of elephantiasis; and that such weakness or anomalies can be inherited.

9. The filaria is an important factor in the production of endemic elephantiasis of some regions, but it is not essential to the occurrence of endemic elephantiasis.

10. Elephantiasis in filarial regions results indirectly from filariasis through bacterial infection.

11. Sporadic lymphatic elephantiasis and endemic elephantiasis are not essentially different.

CONGENITAL OPHTHALMOPLEGIA EXTERNA.

BY S. G. WEBBER, M.D., BOSTON.

CONGENITAL ophthalmoplegia is a rather rare condition. In the medical journals and reports of the last thirty years I have found records of only seventy-four cases. Most of these were in journals or memoirs devoted to affections of the eyes, only a few appearing in those dealing with diseases of the nervous system.

It is some years since I saw Mr. S. His birth had been difficult, instruments having been used.

Since infancy there had been strabismus of the left eye; irregular movements of the head and left hand. There had been, at least at times, sugar in the urine. He was said to have a peculiar gait in walking, unsteady, with much motion of the body and head. No history of other peculiarities during his earlier life could be obtained. He was fond of study and of reading. He had graduated from college.

He had never had any severe sickness, nor any injury, was not strong, had a delicate stomach, was very nervous. He had run down from worry as to his mother's health and from close application to his studies; he had an attack, which was called grippe, after which there had been intestinal disturbance, attended with a looseness of the bowels. For a while he had passed three or four quarts of urine in twenty-four hours, which was said to contain sugar. During his last year in college he was obliged to stay in bed much of the time, studying in bed.

His eyes were almost immovable, no motion being more than a few lines in extent. In reading he moves his head from left to right and back to left, following the lines of print across the page. When closed, the lids are tremulous; they do not fully close, especially the right. The right pupil reacts to light only in sympathy with the left; if the right is exposed alone it remains about one half dilated. The left pupil reacts normally to light. For near vision both pupils react slightly. The field of vision is nearly or quite normal in both eyes. Both disks are indistinct in outline, the left the more so; the vessels are clear in their whole course; there is no distinct cupping.

When not reading there is a constant, not extensive, rotation of the head to the left, then back to the median line, irregular, slow, not jerky. The left hand is kept by his side, fingers closed; the right hand by his side, fingers extended; at times there is an athetosic movement of the fingers, more on the right. He can perform all motions; touches his nose readily, with fingers of either hand, with his eyes closed. When the arms are extended there is a tremor of the right; the left is nearly steady. The tongue is protruded with a motion of the tip athetosic in character. He walks without trouble, slightly unsteady. Knee jerk and plantar reflex are normal. When seen, no sugar in urine.

About two years after I saw him Mr. S. died. As he lived at a distance from Boston, I did not learn of this until some time later.

This affection is of special interest as being not only congenital, but also a family disease, and in many cases hereditary. It deserves as much consideration as other family diseases. Thirty-three persons belonged to only nine families, two or three generations being affected. In five families, including twelve persons, only one generation was affected. In one family in a collateral branch, cousins, were said to have had the same defects as the two brothers. (Reported by 11.) That is, in fourteen families, more than one in each family, forty-five in all, suffered from congenital ophthalmoplegia externa in a greater or less degree. In twenty-nine families there was one patient in each family.

Of the seventy-four cases of which reports have been found, 45 were males, 27 were females; the sex of 2 is not given.

The amount of loss of power in the muscles varies greatly in different cases, and in different muscles in the same case, from a slight impairment to complete loss of power. The muscles on the two sides may be unequally affected; often only one or two muscles are paralyzed. Sometimes the internal rectus is paralyzed so it does not act alone, but it will act in conjunction with the external rectus, as it has two sources of innervation. In a few cases the superior rectus is said to have been paralyzed, yet when the lids were closed the eyes rolled up as if the superior rectus acted.

The amount of loss of action in the levator palpebræ varies greatly; sometimes the lids cover the whole cornea, generally only a part, and usually the amount of paralysis is not equal on the two sides. Very often the frontalis enables the patient to raise his lids enough to uncover at least a part of the pupils. Sometimes an extra strong exercise of the will enables the patient to move his eyes through a small arc in certain directions, but this power is soon exhausted.

In most of the reports the oblique muscles are not mentioned and it is very difficult to determine from the description of the symptoms whether or not they were paralyzed.

A large majority of the patients had some defect in vision, either diminished visual power or some refractive error. The pupil reflexes were impaired in only three cases. Diplopia was rare. The fundus was usually normal.

In twenty-eight cases all the recti were more or less paralyzed. In ten cases the recti innervated by the third nerve alone were affected. The external rectus alone was paralyzed in fourteen cases; the levator palpebræ in fifty-three cases.

The pathological changes which cause congenital ophthalmoplegia externa may be found in the muscles or in the nerve nuclei in the medulla. It is not likely to be in the nerves as the paralysis is too sharply limited to a few muscles for the lesion to be where the fibers for so many muscles lie as near each other as they do in the third nerve.

In six patients (reported by 3, 13, 30, 33, 34, 37), there has been found a change in the structure of the muscles when an attempt has been made to correct strabismus by an operation; the muscles were either wanting or were reduced to mere fibrous bands, or were evidently very weak, yielding readily to slight traction. In one case (reported by 19), the patient died from diphtheria and an autopsy showed that one levator palpebræ superior was wanting, the other very weak; the recti and oblique muscles were inserted abnormally in the globe so they could not move the eyes in the proper directions. Having found the muscles thus affected in so many cases, all in which there are reports of operations, it is probable that the same condition exists in many others.

Several authors have entirely ignored the pos-

sibility of a muscular origin and have referred all cases to nuclear origin. No examination of the nuclei of the nerves in congenital cases has been found. Several times in ophthalmoplegia externa not congenital, such changes have been recognized, and probably they exist in many of those in our list.

As the nucleus of the superior and inferior recti is distant from that of the external rectus, and there are no commissural fibers connecting these nerves, as are found between the internal and external recti, a single lesion could not be the cause of the impaired innervation of all these muscles. In those cases where all the recti acted imperfectly, was there defect in the insertion or development of the muscles due to some vice of intra-uterine growth, as was found in a few cases; or were the nuclei of the third and sixth nerves at fault from some intra-uterine affection similar to polio-encephalitis?

In six cases (reported by 7, 8, 9, 16, 17) there was loss of power or paralysis in the external rectus and the facial muscles. The sixth and seventh nerves do not run near enough to be affected by the same lesion after leaving the medulla without other nerves being also implicated. Only where they are adjacent in the medulla, where the fibers of the seventh curve around the sixth nucleus at the eminentia teres to pass to its nucleus, do the two nerves lie so near that both are liable to be exposed to the same morbid changes. In these cases the lesion was undoubtedly at or near the nuclei of these nerves.

In two cases (reported by 4, 29), there were difficult births; in one, softening of one side of the pons and of the right corpora quadrigemina was found as result of injury at the time of birth. In my case there was also difficult birth and the cerebral lesion extended beyond the origin of the motor oculi nerves.

It is evident that lesion of the nuclei in the medulla is sufficient to produce paralysis of the muscles of the eye and probably that is the only pathological change in many cases. Whether such a lesion is the cause of the change in the structure of the muscles found in so many patients, we do not know, as post-mortem examinations have been lacking. This is a field for future investigation.

The distribution of the blood vessels in the medulla, the floor of the fourth ventricle and the aqueduct explains the limitation of the lesions. The arteries entering the mid-brain are very small, are end-arteries; they have very limited or no anastomoses and each supplies only a small area of the cerebral substance. An occlusion or narrowing of the caliber of one of these arteries would deprive a very limited area of its normal blood supply without affecting neighboring areas, hence only one or a few groups of nerve cells would be destroyed or their activity seriously impaired. The general freedom of the intrinsic muscles would be explained by the more anterior situation of their nuclei, probably insuring them a larger and more certain blood supply.

In six cases (reported by 8, 9, 11, 16, 23), there were clearly other signs of defects in intra-uterine growth, as feeble memory, deformed hands and feet, clubfeet, right hand wanting and right arm short, muscles generally flabby and weak, absence of patella and Achilles reflexes.

Why should the condition be hereditary or a family peculiarity in so many cases?

THE TECHNIC OF ARTHROTOMY. A REPORT UPON AND DISCUSSION OF ONE HUNDRED AND NINETY-EIGHT CASES.

BY CHARLES F. PAINTER, M.D., AND ANDREW P. CORNWALL, M.D., BOSTON, MASS.

(From the Orthopedic Clinic of the Carney Hospital.)

[Continued from No. 18, p. 692.]

ERASIONS.

(Female.)

CASE 94. M. F., female, nineteen, single. Operation, July 17, 1903.

Same incision used as for complete excision of the knee-joint. When joint was opened and knee flexed, a small pannus was seen beginning to encroach upon the cartilage of the femur. A small area of soft bone and thin cartilage was noted on the inner aspect of outer condylar articulating surface. This area was excised and pannus removed. Head of tibia and remaining portion of joint normal in appearance.

Discharged Aug. 19, 1903, wearing plaster cast.

May 18, 1904. Ten degrees motion in joint. No swelling or sensitiveness. Wearing leather cast.

June 1. Omit cast four hours daily.

July 6. Pain from over-use during past two weeks. No evidence of renewed activity of disease.

1908. Patient has never had any recurrence of the disease, but has no motion now in the joint.

CASE 95. S. B., female, fifteen, single. Operation, Aug. 28, 1903.

Same incision as for excision. Joint fluid, wine color in appearance. No flocculi present. A considerable amount of adipose tissue, "boggy" in nature, distributed throughout joint, some of which resembled granulation tissue. Most of this tissue was adherent to internal condyle of femur and showed a tendency to encroach upon its cartilaginous surface. Joint cartilage showed its only abnormality in a lack of luster. All abnormal tissue was removed and cartilage carefully curetted so as not to injure normal tissue.

Sept. 14. Discharged wearing cast.

Oct. 17, 1905. Knee has remained stiff since operation. Under anesthesia knee was manipulated and a few degrees of motion obtained.

Oct. 26. Patient has a few more degrees of motion than when she returned to the hospital. Discharged unrelieved.

April 4, 1906. Motion of 15°. Walks with limp.

CASE 96. H. R. C., female, twenty-three, single. Operation, Aug. 17, 1904.

Same incision used as for excision. As soon as joint was opened a small amount of straw-colored fluid was liberated and a few grayish-purple granulations protruded from the wound. The entire anterior surface of joint was covered with this same tissue. Immediately below internal condyle of femur a similar mass of tissue was found, which when excised and when opened proved to be cystic, contained cheesy material and clear fluid. The external and internal condyles were covered with a purple pannus. All pathological soft parts removed and pannus curetted off as much as possible. Patellar ligament restored with three heavy silk sutures. Posterior wire splint.

Aug. 25. Cast applied. Pain upon attempted motion. Discharged home.

Ultimate result was a pathological cure and ankylosis.

CASE 97. A. E., female, twenty-four, single. Operation, Nov. 19, 1906.

Same incision as above. When joint was opened a small amount of straw-colored fluid containing "rice bodies" escaped. Synovia redundant and rice bodies attached. Pockets behind the crucial ligaments containing this same material were excised. Bursæ between semimembranosus and tendinosus similarly treated. One small focus curetted out from anterior aspect of inner tuberosity of tibia. Partially detached portions of the semilunar cartilage removed and areas curetted from the cartilaginous surfaces of both bones. Posterior wire splint.

Dec. 3, 1906. Plaster cast applied ankle to groin.

Jan. 1, 1907. Cast changed and patient discharged to St. Luke's Home.

During the following year the patient gradually improved and obtained a little motion, but not enough to be of practical value to her. She then went to her home in Sweden and reports (1909) that she has not been able to work because of the poor motion in the joint. There does not seem from her description to be any sign of disease.

There were 13 erasions, — 9 in men, 4 in women. There was one slight skin infection among these. One case was so bad when we got inside the joint that an excision was attempted, but the disease extended so far into the tibia that a thigh amputation had to be done. He is now (1910) using an artificial limb and has had no trouble from the leg. One of these cases was a wrist. The others were all tuberculous knee-joints. There was one death among this group and that was a few days after leaving the hospital and was due to tuberculous meningitis.

It will be observed in studying the cases in this group, viz., the excisions and erasions, that the danger of disseminating a tuberculous infection through surgical procedure is not a wholly negligible matter. Care must be exercised to allow nature to start her protective immunizing processes, both local and general, before one takes the risk of opening up new tissue to infection and absorption.

Our technic of approaching the semilunar cartilage has undergone more changes than that of any other operative procedure upon the joints. The great difficulty is to persuade oneself to get the center of the incision far enough down upon the femoral condyles. The modification of the method employed which was suggested by Mr. Robert Jones, of Liverpool, has proved most helpful. By making the skin incision a straight one, having its center over the line of the joint, and then flexing the leg over the end of a table, the cartilage will present at once when the capsule is incised. The removal of the detached portion should then be accomplished, using either a tenotome or a long-handled, short-bladed pair of scissors. Nothing but the instruments ever need enter the joint cavity. The capsule should be closed carefully and by a separate row of catgut sutures which should be sufficiently resistent to digestion so that they will remain at least three weeks. Then close the fibrous capsule by a second row of such sutures and the skin with a continuous catgut or an interrupted silkworm gut. If there is much ooze in the joint, it is better to use interrupted sutures and insert a pedicle silk seton for thirty-six hours.

Fixation in plaster or upon posterior wood or wire splints after the operation has been abandoned at this clinic because there seemed no surgical advantage during the first week, and after that period mobilization is what is desired, and that can best be secured by not having any initial stiffness due to splinting to overcome. Passive motion, fomentation and massage are indicated at the end of the first eight days, and in the course of the third week right-angled flexion should be secured, and then weight-bearing and voluntary motion may be permitted. A flannel or a "Bender" bandage should be worn for a month or six weeks, and massage had better be continued throughout this entire period. The removal of joint mice requires no essential modification in technic, except that it is well to know that the back of the knee-joint is readily reached by an incision through the popliteal space, care in avoiding the vessels and nerves in this situation being the only thing of special importance. In certain cases the mice are only to be found in this posterior pouch of the joint. It is not safe to attempt the

removal of these loose bodies under local anesthesia. They may slip away, and in attempting to find them there is great danger of breaking the asepsis and infecting the joint. It is always best to search for more than one, though only one may have presented itself. They often hunt in pairs. The greater frequency of the occurrence of displaced internal as against external cartilages has been emphasized by our experience. We also would call attention to the constancy with which the semilunar displacements are accompanied by hypertrophy of the alar ligament nearest to the dislocated cartilage and the advisability of removing this at the same time that the cartilage is removed.

SEMILUNAR CARTILAGE.

(Male.)

Case 98. J. S., male. Operation, Nov. 15, 1901.

A five-inch linear incision over inner aspect of left knee. Internal semilunar cartilage found detached except at its outer end. Entire inner segment of cartilage removed. Wound closed and light plaster cast applied with leg in extended position. Cast continued one week.

Nov. 22. Discharged. Convalescence uneventful with complete restoration to normal function.

Case 99. F. G. T., male, thirty-seven, married. Operation, Feb. 10, 1905.

Right knee-joint opened on inner side of patella. When capsule was incised about 5 oz. of straw-colored fluid were removed. A hyperemic area was found on cartilage of inner condyle of femur. The anterior and inner portion of the cartilage was dislocated and was removed. Wound closed.

Feb. 24. Discharged. Convalescence uneventful.

Patient had no subsequent symptoms referable to the knee-joint.

Case 100. J. F. S., male, forty. Operation, Nov. 20, 1905.

Left knee-joint opened over inner aspect. When capsule was incised a greenish, semifluid substance was evacuated and the tip of the internal semilunar was found detached. This was removed and a small villous fold attached to inner capsule was also excised and wound closed.

Nov. 28. Discharged.

Patient regained motion rapidly and at last visit to Out-Patient Department had no symptoms from the operated knee.

Case 101. J. McM., male, fourteen, single. Operation, May 18, 1906.

Curved incision made over outer aspect of left knee. Over head of fibula on joint line a mass was dissected away which was found to be a portion of the external semilunar cartilage. The remaining portion was also excised and wound closed.

May 29. Discharged. Convalescence uneventful.

No subsequent symptoms from this joint.

Case 102. T. W., male, thirty-six, married. Operation, June 8, 1906.

Semilunar incision over inner aspect of right knee-joint. Internal semilunar cartilage displaced and there was considerable fatty growth about the ligamentum alaris. The cartilage and lipomatous growths were removed. Wound closed.

June 22. Discharged. Convalescence uneventful.

No history of subsequent symptoms.

Case 103. S. H., male, thirty-nine, married. Operation, April, 1908.

Left knee opened on inner side. Internal semilunar cartilage partially detached. This was removed and also the infra-patellar fat pad, which was larger than normal. Nothing further abnormal found in the joint. Wound closed.

April 28. Discharged. Convalescence delayed by a stitch abscess.

Case 104. H. G., male, twenty, single. Operation, May 19, 1908.

Right knee opened over inner aspect. Internal cartilage only slightly detached and not dislocated. Anterior portion of capsule showed villous thickening. This was removed and cartilage excised.

June 3. Can flex knee beyond a right angle without discomfort. Discharged.

July 10, 1908. Favors knee slightly when walking. Motions normal. No pain or tenderness. R) Hydrotherapy.

Case 105. J. F., male, twenty, single. Operation, May 19, 1909.

Left knee-joint opened on inner side. Considerable excess of fluid. Internal semilunar cartilage folded and anteriorly displaced, but still attached. Whole inner, anterior cartilage removed, which allowed complete extension.

May 25. About 20° active motion.

June 4. Motion to a right angle.

June 11. Motions normal.

Case 106. J. D., male, twenty-six, single. Operation, May 26, 1909.

Left knee-joint opened on external aspect. Subpatellar fat pad enlarged; external semilunar not detached, but easily displaced outward. Portion of fat pad and cartilage removed. Wound closed and light plaster cast applied.

May 31. Motion to a right angle without pain.

June 21. Motion normal.

Case 107. J. W., male, twenty-three, single. Operation, June 7, 1909.

Left knee opened over outer aspect. Considerable excess of straw-colored fluid. Small subpatellar lipoma removed. Loose external semilunar cartilage was also removed. Wound closed and light cast applied.

June 13. Motion to 40° without pain.

June 20. Discharged. Motion to a right angle. Patient was heard from about three months later and reported a perfect return of function to knee.

Case 108. J. C., male, twenty-six, single. Operation, July 28, 1909.

Knee opened over inner aspect. Knee flexed in Jones position and a partially detached cartilage easily dissected out. Wound closed.

Aug. 8. Convalescence normal to date. Discharged to care of his own physician, who later reported a perfect return of function.

Case 109. A. O., male, thirty-four, married. Operation, Dec. 8, 1909.

Left knee opened over inner aspect. Knee flexed as in last case and internal semilunar cartilage found detached and was removed.

Dec. 22. Rapid recovery of normal function, which was preceded by a slight stitch abscess. Discharged.

Jan. 3, 1910. Motions of knee normal. Patient walking about with cane.

Case 110. D. D., male, sixteen, single. Operation, Dec. 29, 1909.

Right knee-joint opened over outer side. External semilunar cartilage partially detached and removed in two pieces.

Jan. 3, 1910. Patient comfortable. No pain or tenderness.

SEMILUNAR CARTILAGE.

(Female.)

Case 111. A. K., female, twenty-one, single. Operation, March 13, 1905.

Right knee-joint opened by 7 cm. incision over inner anterior aspect. When capsule was opened, considerable synovial fluid escaped. Several fat tabs were adherent to the alar ligament and anterior aspect of capsule, several of which were removed. Anterior and inner portion of internal semilunar being partially detached, was excised. Wound closed and light plaster cast applied.

March 25. Active motion, 15°.

March 29. Discharged. Active motion to right angle.

CASE 112. L. E., female, twenty-eight, single. Operation, May 10, 1907.

Incision 2 inches on inner side of right knee. Anterior portion of internal semilunar found loose. This was removed; also the greater portion of infrapatellar fat pad. Four strands silk left between stitches as wick to be removed in three days.

May 22. Passive motion daily. Very little pain. Discharged.

Jan. 2, 1908. Knee is becoming flexed and aches constantly. Re-entered hospital. Right knee in 25° permanent flexion. Extension limited. One cm. atrophy over right patella. A prominent ridge can be felt to inner border of patella. A loose bony fragment seems to be present, sensitive to pressure and the seat of a marked click when leg is flexed. This fragment seems to offer mechanical obstacle to complete extension.

Jan. 3. An anesthetic given and incision made parallel and close to old scar. Line of joint obscured by a fragment of partly cartilaginous, partly calcified tissue, which had the appearance of a displaced semilunar cartilage turned so that the broad surface which is normally attached to the head of the tibia was parallel with the long axis of that bone. The fragment was firmly bound down to tibia by fibrous adhesions. When this fragment was removed the leg could be almost completely extended without force. A few degrees of flexion remain. Plaster cast applied.

Jan. 13. New cast applied. Discharged home.

CASE 113. E. B. M., female, twenty-one, single. Operation, Feb. 11, 1908.

Incision 5 cm. in length over outer side of knee. Anterior border of external semilunar cartilage found detached. This is removed, together with the enlarged infrapatellar fat pad. Plaster cast ankle to groin.

Feb. 19. Convalescence uneventful. No pain. Active motion to 45°.

Feb. 24. Patient able to walk about the room and little discomfort is caused thereby. Voluntary flexion to a right angle. Discharged home.

CASE 114. J. A., female, single. Operation, March 10, 1909.

Incision 3 inches long over inner side of right knee. When knee was flexed internal semilunar cartilage seen to protrude over anterior margin of tibial head. Anterior portion removed.

March 19. No pain or temperature. Wound healed. Motion in the joint to a right angle.

March 23. About on crutches. Discharged home.

Subsequent history, complete return of function in joint.

All the cases in this group did well with the exception of one, and that was No. 110.

She was an hysterical case, and in light of the subsequent history her case is easily understood. The joint eventually was restored to very good function.

JOINT MICE.

CASE 115. C. C., male, twenty-one, single. Operation, Feb. 21, 1906.

Right knee-joint opened over outer side. The foreign body appeared as soon as the capsule was incised. The joint was explored with the finger and no other foreign bodies found.

March 3. Convalescence uneventful. Discharged.

No history of recurrence or further symptoms from the joint.

CASE 116. A. S., male, nineteen, single. Operation, Oct. 10, 1906.

Right knee-joint opened over inner aspect. In synovial pouch at inner side of joint a white, smooth, unattached body, size of almond, was found and removed. A calcareous area in the center was seen when body was split open. Joint opened on outer side and a second foreign body removed. Wounds closed.

Oct. 22. Discharged. Convalescence rapid and progressive.

CASE 117. W. J. K., male, forty-three, married. Operation, Oct. 7, 1907.

Left knee opened over inner aspect. Several osteophytes found on tibial condyle, most of which were removed, and one free body found and removed. Outer side of joint opened and a similar though smaller body removed. Wounds closed.

Oct. 15. Flexion to 90° without pain.

Oct. 19. Flexion beyond a right angle without pain. Discharged wearing flannel bandage. No subsequent symptoms.

CASE 118. E. F. P., male, thirty-two, single. Operation, Dec. 30, 1908.

Examination under ether did not reveal the foreign bodies. Tourniquet applied. Right knee opened over inner aspect. Synovial membrane, quadriceps pouch, and immediately about the incision evidence of capsule thickened as in a villous arthritic condition. Considerable excess fluid containing few inspissated clots of fibrin. Several hypertrophied tags dependent from the alar ligaments. In the mid line of the joint below the patella and attached to infrapatellar fat pad was a small dependent calcareous tag which was excised, and measured $\frac{3}{8}$ by $\frac{1}{4}$ inch. Two small loose bodies found in posterior part of joint by forcible pressure on the popliteal space. Margin of trochlear surface hypertrophied throughout. In places this hypertrophied tissue overlaps the bony surfaces beneath. Patella presents broad surface at base due to this pathological condition of cartilage. Small scars on femoral condyle indicate the site from which these loose bodies were detached. Irrigated with sterile water and wound closed.

Jan. 12. Discharged after a normal convalescence.

CASE 119. W. M., male, fourteen, single. Operation, June 25, 1909.

Joint opened on inner side. No fluid. Beneath hamstring tendons was found detached a large, round, hard mass, size of a cherry. Rough area in inner condyle showing place of detachment. Wound closed.

June 28. Motion to right angle.

July 6. Discharged. No recurrence of symptoms to present date (1910).

As in the cases of semilunar operations, the results have been good, and no untoward circumstances attended any of the cases. We would urge the importance of avoiding operative interference in these cases until after the joint had been kept at rest for a few days and the traumatic exudate had become absorbed and the injured synovia had become quieted down.

VILLOUS ARTHRITIS, INFECTIOUS ARTHRITIS.[4]

This group is concerned chiefly with the knee-joint, though some other articulations are in-

[4] In this group the joint lesions were generally polyarticular, but the larger joints of the locomotive apparatus were the ones subjected to surgical treatment.

cluded in the list of cases. The technic employed is similar to that in other arthrotomies, at least as far as the methods of performing the operations are concerned.

We have often employed two straight incisions on either side of the patella. With scissors the large fringes and villous enlargements are removed. The bases of these fringes cicatrize and the synovial membrane grows over the base. It is well to wash out these joints with hot, sterile salt solution before closing the capsule, and they ought always to be drained with setons for forty-eight hours. Early manipulative treatment should be the rule in these cases. The therapeutic conditions met by arthrotomy in these cases are (1) the removal of toxins which, if allowed to remain, would be damaging to the joint; (2) the removal of the products of the previous inflammatory conditions even when they are not capable of exerting any toxic influence upon the joint; and (3) the removal of fringes whose presence in the joint are a mechanical irritant preventing the restoration of the synovia to a normal condition.

Physical therapy, principally in the form of stimulating douching with hot and cold water, protective splinting to guard against overstrain, and bandages to keep down swelling and control the extremes of motion, are indicated. Massage has to be guardedly employed in these cases, particularly where the infection has been a recent one.

The growth of a pannus over the margins of the articular cartilage should be removed where it is evident by an arthrotomy, for its persistence inevitably means cartilaginous erosion.

INFECTIOUS ARTHRITIS.

(Female cases.)

Case 120. A. D., female, twenty-six. Operation, July 30, 1906.

Curved incision over outer side of right ankle and capsule of cuneiform-metatarsal articulation exposed. Cartilage lifted off anterior articular surface of cuneiform. A section of the cuboid was removed. No pus found.

Aug. 7. Stitches removed. Slight serous discharge. Plaster applied, with window for dressing.

Aug. 14. Discharged.

Case 121. S. A., female. Operation, Feb. 19, 1901.

Linear incisions made on either side of the patella. All capsular adhesions were broken up above and below patella. Small area of roughened bone noted on under surface of patella. Wounds closed, leaving gauze wick under patella.

Feb. 22. Patient has required sedatives to relieve pain in joint. Gauze wick removed under anesthesia and posterior wire splint used.

April 15. Discharged home.

Case 122. J. P., female, twenty-three, single. Operation, Aug. 27, 1901.

Linear incision 8 cm. over outer aspect of left knee. Capsule thickened, and when incised about 20 ccm. turbid fluid escaped. Several small synovial outgrowths were present, which were excised. Joint cavity irrigated with hot bichloride solution. Plaster bandages applied to leg. A study of the fluid shows abundant pus cells; no bacteria; culture negative.

Sept. 4. Wound clean. Hot fomentations b. i. d. Discharged.

Case 123. K. F., female, sixteen, single. Operation, Sept. 3, 1901.

Right knee opened over outer anterior aspect. Capsule found very thick and vascular. Joint cavity was small. Some fluid present which contained flocculi of fibrin and blood clots. A few synovial "tags" were removed. Hot corrosive irrigation. Plaster of Paris bandages to leg.

Sept. 11. Cast split. No pain except with motion.

Sept. 18. Stitches removed. Wound clean. Pain and tenderness on motion.

Sept. 19. Leg manipulated to 40° under ether.

Sept. 25. Passive motions daily. To leave off cast two hours daily.

Sept. 29. Under anesthesia complete flexion and extension obtained.

Oct. 4. Passive motion to 80°. Left in this position two hours, then flexed and split cast replaced.

Oct. 9. About on crutches. Ninety degrees flexion possible.

Oct. 13. Passive motion to right angle without pain. Active motion limited. Discharged home.

Case 124. A. L., female, fifteen, single. Operation, March 4, 1904.

Incision over inner side of right knee. About 2 oz. of creamy, pale yellow fluid escaped upon opening the capsule. Synovia thickened, hemorrhagic, and presented several ragged tags, .5 to 1 cm. in length. These were removed. Joint irrigated with hot salt solution. No wick used for drain. Plaster cast.

March 14. Cast split. No pain accompanying the slight amount of motion tried.

March 15. Flexion of 15° obtained.

March 18. Under ether leg flexed beyond right angle, causing the rupture of several adhesions. Leg put up on pillows in position of 45° flexion.

March 23. Flexion to 90°.

March 29. Complete extension impossible, owing to thickening of soft parts. To use hot and cold showers at home.

Case 125. A. O'N., female, forty, married. Operation, May 6, 1904.

Inner condyle of left femur exposed through long linear incision through an excess of subcutaneous fat. Synovial membrane seemed converted into a more or less lobulated mass of fat, and joint cavity smaller than normal. Along the border of the condyle the cartilage was hypertrophied and formed a shelf-like projection extending upward ½ inch on the femur. This ridge seemed to be composed of irregular squares of cartilage. The upper edge of the patella presented a similar pathological process. A slightly vascular pannus was situated beneath the projecting ledge of cartilage. Both were removed and joint cavity closed. Plaster cast applied.

May 9. Pain in the knee for two days, but not complained of to-day. Cast removed.

May 25. Convalescence uneventful. Good motion. Advised hot and cold showers at home.

Specimens show hypertrophic arthritic condition. Ultimate good operative result. Had a similar set of symptoms with other knee which improved without operation.

Case 126. L. L., female, thirty-two. Operation, Dec. 8, 1905.

Left knee, left elbow and both wrists manipulated four days preceding without relief.

Incision 8 cm. over inner border of left knee. Subcutaneous tissues very vascular. When capsule was opened, the synovial membrane measured 0.4 cm. in thickness, its surface thrown into purplish ridges. Joint fluid normal in amount. Attached to the alar ligaments

was found a large fringe 3 cm. long, 2 cm. wide, movable and attached by broad base. Several small fringes found throughout the joint. A few patches over middle of external condyle, but no definite erosion. Two spine-like processes on the under surface of the patella, which probably caused the conditions on the trochlear surface above mentioned. Plaster cast with leg in extended position. Fingers, left elbow and wrists were again manipulated.

Dec. 9. Plaster casts split on account of pain.

Dec. 19. Tonsillitis accompanied by excerbation of knee symptoms readily yielded to treatment.

Dec. 22. Cast removed.

Dec. 26. Only 10° motion of knee; joint very sensitive.

Jan. 2, 1906. Discharged relieved. Motion in knee gradually increasing.

CASE 127. M. T., female, fifty-three, married. Operation, Jan. 21, 1905.

Under anesthesia knee was forcibly flexed and extended a few degrees. Patellar adhesions prevent further motion. Incision made over inner aspect of right knee. Synovia very vascular. Patella freed with blunt dissector and chisel. Considerable gain in extension, but incomplete owing to contracted hamstrings. The internal hamstring was tenotomized. Plaster cast applied with leg fully extended.

Feb. 3. Convalescence uneventful. Discharged.

CASE 128. F. L., female, twenty-four, married. Operation, Aug. 16, 1907.

Incision 4 inches long over the outer side of left knee. Large prepatellar fat pad. Also large amount of disintegrated fat found in joint and removed. Capsule and surrounding tissues congested.

Aug. 29. Convalescence uneventful until yesterday, when, without instructions, patient bore her weight upon knee. To-day complains of considerable pain.

Sept 12. Except for above indiscretion and temporary results, convalescence progressive. Discharged home.

CASE 129. A. G. G., female, twenty-three, single. Operation, Feb. 19, 1908.

Left knee-joint opened by linear incision over outer side. Synovia thick and fibrous. Joint cavity small owing to adhesions in quadriceps pouch and between patella and femoral condyles. Patella freed by instruments, in consequence of which complete extension and flexion were possible to a right angle. Plaster cast applied with leg in full extension.

March 4. Discharged relieved.

CASE 130. J. L., female, twenty-seven, married. Operation, Oct. 14, 1908.

Left knee-joint opened over inner side. Capsule thickened. Patella adherent and quadriceps pouch obliterated by adhesions. Adhesions freed and joint irrigated with hot corrosive solution. After closing joint 3 oz. of sterile olive oil was injected under patella.

Oct. 21. Leg manipulated under ether.

Oct. 28. As knee is too sensitive for any passive motion, an anesthetic was administered and leg manipulated, after which procedure 3 oz. of oil was again injected under patella.

Nov. 4. Moderate swelling of joint. Very painful when motion is attempted. About 5° motion in flexion. Sensitive over internal condyle. Patella barely movable. Discharged home before it was advisable, owing to family difficulties. Neglect and improper treatment followed and a bad result obtained.

Jan. 1, 1910. Knee very sensative to jar or motion. A few degrees flexion possible. Probable Neisser infection.

CASE 131. M. O'C., female, twenty-seven, single. Operation, Jan. 13, 1909.

Incision made over inner side of right knee. Quadriceps pouch bound down with adhesions of the organized exudative type. These were wiped out with sterile gauze and joint irrigated with hot salt solution after knee had been flexed to a right angle.

Jan. 16. Patient has run a subnormal temperature since she entered the hospital. Knee very sensitive to passive motion beyond 15°.

Jan. 27. About 20° passive motion and 10° active without discomfort to patient.

Feb. 3. Under ether adhesions were broken up when leg was flexed to a right angle. About 2 oz. of sterile olive oil was injected under patella and leg again flexed.

Feb. 17. Same procedure as in last note.

Feb. 20. Discharged. Gain in motion has been progressive but slow. The general condition of the patient was below par when she came under hospital treatment due to toxemia from long-standing Neisser infection. A miscarriage of four months while in the hospital also retarded convalescence. Fair delayed result, however.

CASE 132. E. W., female, twenty-three, married. Operation, April 7, 1909.

Skin incision as for excision of joint except that on outer side it was carried about one inch above top of quadriceps pouch. Patellar tendon cut and flap containing the freed patella dissected back. Fibrous ankylosis throughout the joint. This was broken up with knife and chisel and leg flexed to right angle. Skin was dissected back and long flap of adipose tissue with pedicle to outer side was dissected out, turned down between opposing bony surfaces and sutured, after first removing a thin slice of the lower end of the condyles. Patellar tendon restored with silk. Plaster cast applied.

April 19. Window cut and superficial slough found over inner condyle.

April 26. Cast removed and posterior wire splint substituted. Evidence of large slough over patella.

May 1. Large area of skin removed due to its gangrenous condition and hot enzymol packs continuously applied. This slough due to cutting the flap too near the skin.

May 7. Wound clean except for small area above tibial tubercle. Dressed with balsam Peru.

May 27. Some motion in knee, but little attempt made to move it on account of interfering with granulations.

June 2. Skin grafts taken from opposite thigh and transferred to granulating area over knee.

June 9. Three long skin grafts taken and wound covering over rapidly. Discharged home to-day.

CASE 133. J. S., female, forty-nine, married. Operation, July 9, 1909.

Incision outer side of right knee. When capsule was opened a large amount of red granular material was evacuated. A small lipoma was found under patella and removed. Numerous fringes removed and joint wiped out with sterile gauze and then irrigated with hot salt solution.

July 12. Patient has been very comfortable and is out of bed.

Aug. 1. Continues very comfortable. Swelling of fingers has subsided. Measured for caliper splints and discharged home.

The results of the previous series of operations have been quite satisfactory when the conditions for which they were performed are taken into consideration. One case of arthroplasty of the knee is included where it does not perhaps properly belong. There were no infections or

serious complications in any of the cases and motion was secured to certainly as great an extent as it was present before the operation, and in many cases it was greater. Even where the motion was not increased, the function of the joints was often markedly improved and the progress of the disabling arthritis in that particular joint at least was checked or retarded. Improvement in general condition was often associated with the removal of the contents of these infected joints. Toxic absorption from these chronic joints as well as from the more acute ones goes on to a considerable extent in many cases and evacuation of these toxic materials is important.

Case 134. J. W., male, thirty-six, married. Infectious arthritis. Operation, Feb. 3, 1905.

Right elbow-joint opened by incision 8 cm. in length over outer aspect of joint. When head of radius was exposed, the cartilage covering the head was redundant and a portion of this was removed. A similar incision made over inner side of joint and ulnar head exposed. The same pathological condition was found to exist there also. Arm could then be brought to within 5° of a right angle. Arm put up in extreme flexion. Left arm also put up in cast.

Feb. 7. Some swelling of right hand. Plaster removed and extension held by bandages.

Feb. 14. Plaster reapplied.

Feb. 25. Both arms manipulated under ether, and cast reapplied to right in flexion.

March 9. Discharged. Left arm much improved.

April 10. Flexion of right arm to right angle; extension to 35° beyond a right angle. Left elbow to 107° and extended to 40° beyond a right angle.

Case 135. H. L. F., male, twenty-four. Operation, Dec. 21, 1901.

Incision made parallel to sheaths of perineal tendons, left foot. These were found thickened, but not infiltrated. Incision carried forward over joint between the cuboid and astragalus; the joint was opened, exposing two small fringes and an overlapping ridge on the astragalus, all of which were removed and the wound was closed.

Patient discharged in ten days.

Case 136. J. B., male, forty, married. Operation, May 14, 1902.

Left ankle-joint opened by two incisions, one parallel with peroneal tendons, the other parallel with the tibialis posticus tendon. Several small vascular fringes found and removed. Cavity then lightly curetted and washed out with sterile water. Peroneal tendons divided in order to facilitate access to the joints of the posterior tarsus.

June 4. Convalescence uneventful to date. New cast applied and patient discharged relieved.

Case 137. N. F., female, atrophic arthritis with synovial hyperplasia (early), forty-eight, married. Operation, Jan. 27, 1904.

Usual linear incision made over inner side of right knee. Capsule found thickened to about 1 cm., and of a grayish gelatinous appearance. A small amount of clear, yellow fluid was enclosed. Digital examination revealed one small tab from synovial surface in lower angle of wound which was removed. Similar incision over outer side of joint, and a few small tabs found similar in nature to above. Synovial membrane was everywhere thickened and congested.

Wounds closed and plaster cast applied.

Feb. 2. Cast removed. Wound clean.

Feb. 4. Knee can be flexed 15° without force.

Feb. 8. Passive motion daily. To-day 50° motion possible in flexion. No power of voluntary extension after passive flexion.

March 1. Has been wearing caliper splint during day over flannel bandage. Knee can be flexed to a right angle easily.

Discharged home.

Case 138. M. F. Operation, Nov. 8, 1908.

Both knees were forcibly extended. Both patellæ can be moved slightly and no crepitation elicited beneath. Capsule of knee not thickened, but synovial membrane adherent throughout considerable part of the joint, thus diminishing the size of the cavity very materially. No motion possible in flexion. On exerting moderate degree of force, adhesions were broken up, apparently more between opposing layers of capsule than between the bones of the joint. About 25° of flexion secured in both knees. More could have been obtained, but at too great risk of trauma to joint.

After manipulation, about 3 oz. of sterile oil injected under inner side of patella; considerable pressure necessary. The effect of the injection was apparent in the separating of the opposing layers of membrane as the distention of the capsule progressed.

Dry sterile dressing and bandage.

Nov. 12. Patient complains of great tenderness in both knees. No attempt made toward passive motion.

Nov. 23. Oil has apparently been entirely absorbed in both knees. Both patellæ freely movable, but very slight motion of either knee can be obtained in flexion. Tenderness persists.

To have massage to thigh and calf.

Dec. 9. Operation.

Regular U-shaped incision made with apex over tibial tubercle. Skin flap dissected back and joint opened. Adhesions broken up with fingers in quadriceps pouch. Capsule opened on inner side and remaining adhesions broken up. Patellar tendon divided midway between patella and its attachment, under surface much eroded and a small portion was removed with chisel. Leg forcibly flexed and many adhesions broken up between femur and tibia; both surfaces much eroded. Latter surfaces curetted. Head of femur covered with four layers of Cargile membrane, which was sewed to fascia with catgut. Head of tibia treated in like manner. Bones then approximated with extension to prevent tearing of the membrane. Patellar tendon united with several strands of silk. Capsule closed with interrupted silk sutures and skin with interrupted catgut. Attempt to introduce oil in joint failure, as it oozed out between the stitches.

Patient suffered slightly from shock.

Dec. 11. Patient has temperature of 101°. Pulse, 110. Respiration, 22. Plaster cast split owing to edema of foot, and flannel bandage applied to lower extremity.

Dec. 17. Wound in good condition. Posterior wire splint applied.

Jan. 18, 1909. Wound dressed. Silk suture removed from sinus external to tibial tubercle.

Jan. 27. Operation. Right leg manipulated and 20° motion obtained without much force. Considerable serous ooze from old incision.

Feb. 7. After the manipulation temperature shot up to 103°. Skin wound partially broke down. Culture showed pure staphylococcus aureus. Hot boric acid poultices applied and infection readily yielded to treatment.

Feb. 15. Wound broke down on outer side (over exterior condyle another stitch removed).

Feb. 26. Wound gradually healing. Three stitches (silk) have been removed. Sodium chloride and citrate solution applied. Dry dressing and bandage.

March 10. No discharge. Wound practically closed. General condition of patient fair.

March 19. Patient sitting up to-day. No pain or temperature. Very slight motion of knee can be obtained.

April 4. Discharged home.

Patient had general atrophic process for a long time before the last operation, and same had been slowly progressive. It remains an open question as to the advisability of using Cargile membrane and as to operating upon cases with this diagnosis. Certainly no advantage has been gained from the arthrotomy in this case. Considerable difficulty was encountered from subsequent sloughing of the silk sutures used at time of operation. The entire Cargile membrane has sloughed out and there has been no benefit to the patient for all her suffering. The knees are straight and stiff, but there is so little power in her arms and hands that it is impossible for her to get up on her feet. The pain has largely disappeared.

(To be continued.)

Clinical Department.

CUTANEOUS DIPHTHERIA. FATAL PRIMARY CASE.*

BY EDWIN H. PLACE, M.D., BOSTON,

Physician in Chief, South Department, Boston City Hospital; Assistant in Pediatrics, Harvard Medical School.

CUTANEOUS diphtheria associated with diphtheria of the respiratory tract is not particularly uncommon. It has been seen at the South Department during the past three years in the following conditions:

(1) About the face and hands, often appearing much like an impetigo contagiosum, less often with distinct membrane. Cultures show virulent Klebs-Loeffler bacilli, and both types clear rapidly with the administration of antitoxin.

(2) On the auricle, chiefly the concha, extending from the middle ear; and behind the auricle inoculated upon the eczema so common in this region in children.

(3) Inoculated upon lupus vulgarus lesions on the face, following curettage.

(4) In wounds and abcesses on the neck and face.

(5) Inoculated upon varicella lesions, most commonly on the vulva or vagina.

At times it is severe in these locations, and similar cases of cutaneous diphtheria have been known to be the cause of small epidemics. That it may be fatal the following case shows. I am indebted to Dr. John H. McCollom for the privilege of reporting it.

H. B., age seven months. Admitted to the South Department March 24, 1908, referred by Dr. J. S. Stone, from the Children's Hospital Out-Patient Department.

Family history. — Negative.

Past history. — Breast fed. Had always been well except for eczema of pubic region, groins and thighs since birth.

Present illness. — Two days before admission, swelling and redness became marked over the area of the abdomen, genitals and thighs covered by the diaper. There was a considerable thin discharge. Feverish and fretful.

Physical examination. — Conscious, marked prostration. Well developed, fairly well nourished. Mucous membranes of mouth, throat and nose show nothing abnormal. No nasal discharge. Neck negative. Heart action rapid, 140, first sound softened, no murmurs. Lungs normal except for a few crackling râles at both bases.

Over the lower third of the abdomen, the vulva, perineum, anterior part of buttocks and the upper quarter of the internal surface of the thighs, the skin is markedly reddened, swollen and covered with a grayish hyaline membrane, firmly adherent, and when forcibly removed leaves a granular area which bleeds easily. Scattered through this area, especially the lower part, are small various shaped islands of healthy skin, some connected by narrow bands of healthy skin. No vesicles or pustules. Skin elsewhere normal.

The treatment was antitoxin, 12,000 units, strychnia and boric acid dressings locally.

On the third day after admission the membrane was clearing rapidly. No improvement in general condition; heart rapid and very weak. The temperature was subnormal on entrance, but this day rose moderately. During the day the color became of a peculiar gray shade, the heart weak, rapid, the first sound almost imperceptible. Numerous crepitant râles at the bases. Death occurred at 5 P.M.

Cultures from the skin showed typical diphtheria bacilli, and were identified by Dr. Lawrence Rhea by cultural tests and animal inoculation in the laboratory. Cultures from the nose and throat and from the nose and throat of the mother showed no diphtheria bacilli. The post-mortem showed, beside the skin lesions, some hyperplasia of the lymphoid tissue, "septic" spleen, begining bronchopneumonia of both bases and some pus in the middle ear.

The source of the infection was not discovered. There was no known exposure. Neither this child nor any other member of the family had had a sore throat, coryza or other illness recently. It seems probable that the mother or an attendant must have carried the disease on their hands and infected the eczematous lesions in washing the baby or changing its diaper.

The onset, masked by the previous eczema, was probably not recognized, and not until the process became widespread and the symptoms severe was a physician consulted. The severe systemic symptoms in this case may well be expected when we consider the extent of the membrane and the amount of toxin which must necessarily be absorbed.

CONICAL STUMP AFTER AMPUTATION IN CHILDHOOD.*

BY CHARLES A. POWERS, M.D., DENVER, COLO.

THE patient is a girl of thirteen years whose left arm was amputated in its upper fourth by Dr. L. A. La Garde, of the United States Army, for congenital cavernous telangiectasis eighteen months ago. The condition for which the amputation was done extended from the fingers to the upper and middle thirds of the arm. Dr. La Garde kindly asked me to see the case in consultation with him; he exhibited the little patient at meetings of this society both before and after operation. The amputation stump was in all ways excellent, the flaps were ample, the bone well covered.

Those of you who were here when the patient was shown directly after the amputation may remember that the view was expressed that the bone would "grow down," that the stump would become conical and require bone resection. At this time you see that the prediction has been fulfilled; the stump is markedly conical, the bone presses against the skin, the skin is beginning to be adherent through this pressure. The stump is painful and a suitable amount of bone will be resected tomorrow.[1]

In previous papers[2] I have called attention to the practical certainty that when a little child suffers amputation through the upper part of the arm or the upper part of the leg a conical condition of the stump will result. I have never known this to fail. It occurs because the humerus and the bones of the leg develop in large part from their upper epiphyses. The growth takes place at the upper epiphysis and pushes the bone down into and through the soft parts. When the surgeon does his original operation it is best for him to tell the parents that this will probably take place.

The younger the child, the more frequently will the bone have to be cut off.

Medical Progress.

REPORT ON NEUROLOGY.

BY PHILIP COOMBS KNAPP, A.M., M.D.

[Concluded from No. 18, p. 696.]

THE RÔLE OF EMOTION IN THE GENESIS OF NEUROPATHIC AND PSYCHOPATHIC CONDITIONS.

THE Société de Neurologie and the Société de Psychiatrie devoted four sessions to the discussion of this problem[24] at the first annual reunion of the two societies last winter, dealing with the psychological, physiological, neurological and psychiatrical problems. Janet discussed the question on the psychological side. The reaction of the individual to any special circumstance may often be determined in advance by his constitution and education; in other cases, although the reaction is not organized in advance, there is a partial adaptation to the circumstance; in neither case does he consider that there is place for emotion. There are, however, circumstances for which the individual is not adapted by his previous organization, and to which he cannot adapt himself, although he perceives the circumstances and feels the necessity of reacting to them. In these cases, instead of the useful reaction, there are various disturbances of all the functions of the organism. To these disturbances, coming on under these conditions, he gives the name of "emotion." The disturbances are very complex. There are modifications of feeling, giving rise to fear, anger, shame, indignation, discouragement, despair, pain, or feelings of inadequacy, weakness, incapacity, indecision, etc. There are intellectual modifications, systematized agitations in the form of fears, obsessions and the like, or loss of memory and confusion. There are various disturbances of the visceral functions, boulimia, polydipsia, muscular spasm, vomiting, frequent micturition, incontinence or retention, sobbing, hiccough, cough, groans, laughter, palpitation, vasomotor constriction, increased secretions, anorexia, gastro-intestinal atony, choking, smothering, slow pulse, fainting, vasomotor dilatation, hemorrhages and suppression of secretions. There are also motor disturbances, either in the way of motor agitation or inhibition of necessary action. The entire condition may be regarded as a depression of psychological tension with insufficient adaptation and impotent efforts to remedy the condition. Emotional disturbances do not usually come on until after a latent period, and usually affect chiefly one special function. The exciting cause of the emotion may determine what special function shall be affected; the function which was active at the moment may be the one affected, or any function which was previously enfeebled may be affected. If the disturbance has taken a particular form after the first emotion, it may always take the same form after other emotions. The normal individual speedily adapts himself. If the emotion be intense, long-continued and frequently repeated, or if the individual be weak of will and of low psychological tension, the consequences become serious. Vogt, in the discussion, pointed out that the reaction, although inadequate, was not always useless; that an attack of hysterical sleep, for example, might preserve the nervous system from too great excitement. Emotion may lead to active disturbances, often of sudden onset and disappearance, and states of exhaustion, which develop and disappear slowly. Agreeable emotions, too, may excite neuropathic states. Ballet added that slow and long-continued emotions often gave rise to affective conditions. On the physiological side, Hallion showed that, as a rule, there was a definite relation between the intensity of the emotional shock and the reactions which follow. These reactions are often disordered, but, with moderate emotions, the excitement sometimes leads to a general nervous stimulation which aids the organism to adapt itself to the altered circumstances. Stronger

* Paper read and patient exhibited at a meeting of the Denver City and County Medical Society, Sept. 13, 1910.

[1] Three inches of bone were removed.

[2] New York Med. Rec., June 7, 1890. *Ibid.*, April 7, 1894. Ann. Surg., April, 1900.

[24] Rev. Neurol., xvii, 1551, Dec. 30, 1909.

emotions lead to harmful disturbances, and stronger yet may have depressive effects. The will can modify the mental state somewhat, and thus affect the reactions, but when the reaction has once begun, the will can act only slowly by antagonizing the effect of the emotion, which increases the subsequent nervous exhaustion. The vasomotor disturbances of emotional origin may have a certain mechanical effect by giving rise to cerebral hemorrhage, but, apart from this, it is questionable if they can actually engender nervous affections.

Claude presented the neurological problems. At the basis of all neuropathic states there exists a constitutional modification of the nervous system, structural alterations or more or less deviate functional aptitudes which create a particular state of emotivity. Emotion itself is only an exciting cause, secondary to the constitutional state. Emotivity, often heredity, may also be acquired as a result of education, the manner of living and physical and moral conditions. It may be considered as the manner of perceiving and expressing emotions, and is modified greatly by the repetition of emotions. He raised the question whether a disturbance of emotivity is not a necessary condition which enables emotion to provoke neuropathic symptoms. Emotion does not create the epileptic state, but it often acts as the exciting cause of an epileptic attack or its equivalent, and sometimes as the exciting cause of the first attack. It does not create hysteria, but it may provoke the hysterical manifestation in a subject whose emotivity was previously disturbed and may produce many of the accidents of hysteria, such as convulsions, paralysis or contractures, apart from suggestion. Emotion can give rise to transitory depression in normal subjects and in others may engender various manifestations of neurasthenic states, but it is not probable that emotions, no matter how intense or how frequently repeated, can alone produce neurasthenia. Constitutional weakness and hereditary degeneracy are necessary factors. Emotion may excite choreiform conditions, or myoclonus, but it never causes Sydenham's chorea, although it may aggravate it. It also exaggerates tics, and may put the subject into a condition where tics may develop. Emotions may engender certain pathological states which consist of a permanent exaltation of emotivity and are manifested by reactions of the same sort as those which translate the emotion, but of which the subject is conscious. The most frequent symptoms of these states are sensory disturbances, tremor, asthenia, anxiety, depression and hallucination, and they are especially common in traumatic conditions. Dejerine believes that sudden emotion produces hysteria and gradual and continued emotions produce neurasthenia. Emotion is the most important, indeed, the sole factor in the genesis of both affections. Predisposition, however, seems necessary in all cases of hysteria and in the great majority of cases of neurasthenia. The various symptoms come on without any mental representation, without the subject's knowing how or why, and they are certainly not the result of suggestion. In the vast majority of cases careful inquiry will discover the predisposition. Sollier held that the same emotion could be followed by different effects in different subjects, the emotion permitting the emotivity to manifest itself according to the constitutional type. Janet felt that careful inquiry was necessary to determine a pre-existing emotivity and predisposition. Emotivity was a tendency to replace superior operations of adaptation, which had become impossible, by the exaggeration of inferior operations and especially by visceral agitations. Aboulia plays an essential part in emotivity. Bonnier maintained that many emotional reactions were of bulbar origin and believed that he had repeatedly modified them by the reflex action on the bulbar centers from cauterization of the trigeminal terminations in the nose. Crocq stated that in many cases the predisposition was not hereditary but acquired from bad hygiene, excesses, etc., and that in some cases, where there was no predisposition, a neurosis could be produced simply by nervous shock, which was denied by Dejerine and Sollier, but supported by Ballet and Babinski. Dejerine and Dupré both urged that, if emotion could cause neuroses without predisposition, all persons subjected to emotions would suffer alike, which is not the case. Roubinovitch had studied 126 cases of epilepsy, in 20 of which emotion seemed to have acted as an exciting cause, but on further inquiry the emotion was found to be only of secondary importance. Dejerine had seen two cases in which emotion had produced the first epileptic seizure, but he believed that a special predisposition was essential. Janet thought that emotion often provoked attacks in epileptics and that sometimes it determined troubles which in their further course might lead to epilepsy, or it might modify pre-existing neuroses and transform them into epilepsy. Dufour denied that emotion could produce epilepsy in a person without predisposition, which is sometimes manifested by convulsions in infancy. In discussing the relation of emotion to hysteria it was decided to limit the discussion to hysterical crises, paralyses and anesthesias. Dejerine cited cases to prove that an hysterical crisis may develop spontaneously without any previous suggestion, and added that emotion might sometimes cure hysteria. Sollier thought that emotion never created hysteria, but that it was one of the chief factors in exciting hysterical accidents, most of which are merely phenomena produced by emotion. Babinski admitted that emotion might be followed by constriction of the throat, vasomotor and secretory disturbances, tremor, tachycardia, loss of consciousness, outcries and gesticulations. It may even cause a true crisis in a person previously hysterical, but it cannot produce alone a typical hysterical attack, which is always due either to suggestion or to simulation. Such attacks are now rare, which would not be the case if they were due to emotion. Dejerine admits that the classical attacks that Charcot described are purely artificial. Claude called attention to the fact that a crisis might be produced in the first

instance by emotion and later occur from other influences due to auto-suggestion. The crisis is an emotional reaction, and in an emotional state suggestion acts more readily. Janet could cite many cases where a crisis came on after an emotion, and where later other influences complicated the repetition, but the emotion was the original exciting cause. When a patient sees a crisis and imitates it, there may also be the emotion of fear. Sollier believed that various causes, emotion, suggestion, irritation, contagion and others besides might excite a crisis, which is merely the reaction of the nervous system against the inhibition which has struck it. Vogt maintained that even when there was suggestion, the emotional element associated with the suggestion determined the crisis, and stated that by psycho-analysis he had proved the emotional origin of various crises. In regard to other hysterical phenomena, there was a similar difference of opinion, Babinski contesting that all hysterical conditions were due to suggestion, Dejerine, Pitres, Janet and others insisting that the influence of suggestion was exaggerated. Babinski cited various instances where a large number of persons had been exposed to emotional strain without producing hysterical accidents, but, as Dejerine pointed out, the emotion was not sudden, but foreseen, and, as Janet showed, his data were derived from untrustworthy observations. Neurasthenia, according to Dejerine, is due solely to emotion; overwork, infection and intoxication do not cause it unless emotion be added. It develops only in the predisposed, but the predisposition varies greatly. With this Sollier agreed, but the emotion acts in consequence of the special pre-existing emotivity, which is the special factor, the emotion itself being merely an exciting cause. According to Dejerine, the neurasthenic is exceedingly suggestible, even more so than the hysterical, and is often cured by persuasion, yet the mental state is wholly different from that of hysteria. The hysterical is indifferent, the neurasthenic depressed, obsessed and concentrated on his troubles and exaggerating their importance. Sollier urged that emotion may inhibit functions, as in hysteria; or exhaust them, as in neurasthenia. For Dejerine, asthenia and fatigue are accessory in neurasthenia; there is always an emotional cause. Babinski had found an emotional traumatic neurosis, following the Messina earthquake, in which the symptoms were tachycardia, vasomotor disturbances, tremor, headache, pain, insomnia and anxiety, for which he suggested the name "emotional neurosis," the symptoms persisting for months. Dejerine and Claude both insisted upon the fact that traumatic neuroses did not develop except in the predisposed. After a study of 138 cases of chorea, Souques came to the conclusion that emotion, even occurring in neuropathic subjects, was incapable of producing the disease, which is caused by infection. Oddo, on the other hand, after a study of 150 cases, concluded that emotion was a frequent cause of aggravation, relapse or recurrence, especially in emotional children, and that profound emotion, in 10 cases, actually caused the first attack of the disease, a conclusion to which Crocq subscribed. In regard to tic, Meige held that while emotion could aggravate, it did not create it. Janet accepted this conclusion, but believed that emotion could make tic return after it had once disappeared, and could systematize a tic or alter its form; it could also cause a psychasthenic state in which tic might develop. Raymond maintained that emotion may profoundly affect the brain, disturbing the psychical, motor, sensory, vasomotor and thermal centers and causing reactions of the most varied sort. Against such shocks there is a certain power of inhibition which varies with age, sex, temperament, general health and the frequency of the shocks. Emotion may cause psychasthenia and hysteria without the intervention of suggestion or auto-suggestion in the predisposed, and depressing emotions are a common cause of neurasthenia.

The psychiatrical problems were presented by Dupré, who said that emotion gave rise to a psychical shock which determined effects of excitement, depression or functional deviation, varying with the intensity of the shock and the condition of the subject. The important factor is the constitutional emotivity characterized by exaggeration of the tendon, skin and pupillary reflexes, sensory hyperesthesia, unstable equilibrium of vasomotor and secretory reactions, tendency to spasms, the intensity and diffusion of the physical and psychical effects of the emotions, and insufficiency of motor inhibition, both reflex and voluntary. The pathological manifestations of this emotivity are in the domain of anxiety, under the form of obsessions, phobias and impulses. Dejerine accepted the idea of an emotional psychopathic constitution, but stated that some persons show many external manifestations of emotion, agitation, cries, tears, pallor, flushing, etc., while others show none, yet in the latter the effects may be much more serious. Janet added that the essential thing which caused pathological results from emotion was the impotence of the will, leading to impotent effort and emotional disturbances. Dupré and Régis, however, argued that the emotivity might appear very early, before the will was developed. In regard to obsessions and phobias, Janet believed that the crises, although often in relation with slight emotions, were due chiefly to impotence of the will. Emotions may give rise to periods of depression in which the crises were of much more frequent occurrence. Arnaud contested the idea that emotion was the cause of obsession. The obsession is primary, due to a consciousness of incapacity, and exists before the age when emotion is of much importance. Dupré also claimed that the emotional constitution was the basis of mania and melancholia, which was denied by Janet, who held that the alternations and periodicity of maniacal depressive insanity were not of emotional origin, although emotion might cause the anxious depression of psychasthenia. Babinski urged that emotion never produced maniacal depressive insanity, in which opinion all agreed, and Régis called attention to the influ-

ence of abdominal intoxication as an important factor in the production of melancholia. Dupré, Claude and Janet also admitted that emotion in a number of cases may give rise to a confusional psychosis, which is often transitory, but may become chronic. Dupré also had found, on inquiry of many obstetricians, that emotions during pregnancy have no influence on the mental state of the child, but emotions in the parents at the time of conception do have a decided influence.

It seems clear, from the cases cited in the discussion, that emotion is an important factor in the genesis of various neuroses, such as psychasthenia, hysteria and neurasthenia, and also of some psychoses; that in many forms of nervous and mental disease it may act as an exciting cause, aggravate the condition or excite certain symptoms. Its action is not constant, it affects some persons and spares others, or affects a person at one time and not at another. The factor of predisposition is important, yet, as the discussion shows, it is not easy to prove the existence or non-existence of predisposition. In many cases, too, emotion is only one of various factors which work together to produce the nervous disorder.

Reports of Societies.

THE AMERICAN CLIMATOLOGICAL ASSOCIATION.

WASHINGTON, D. C., MAY 3, 4 AND 5, 1910.

[Continued from No. 18, p. 701.]

DR. W. F. R. PHILLIPS, of Washington, read a paper on

NATURAL AND ARTIFICIAL OR HOUSE CLIMATES.

Dr. Phillips stated that the Association holds that there is something curative in climate and that climate itself is an entity capable of being beneficially used as such in the treatment of certain diseases in particular and, in a less degree, of diseases in general. He is convinced that this is based on facts that have been and can be experimentally demonstrated. Some confusion has arisen because of what different people understand climate to be. He takes Hann's definition of climate as the "sum total of the meteorological phenomena that characterize the average conditions of the atmosphere at any one place on the earth's surface." This includes physical as well as chemical attributes of the atmosphere. There is a tendency to consider that climate is necessarily a natural product and that it can be in no wise an artificial one, — one due to man's direct or indirect activities. Artificial climates are the average atmospheric conditions of our buildings of all kinds, our habitations, our factories, schools, theaters, assembly halls, etc., and the assembling of such into villages, towns and cities and all other natural environments rendered abnormal or artificial by us as the result of man's activities. Indoor atmosphere was contrasted with outdoor atmosphere. Conditions in New England in winter were described. We have certain average conditions of the atmosphere in our houses that are deserving of being called climates and that these climates are largely postulated by our outdoor atmospheric environment or climate. Our whole problem of heating and ventilation is a struggle at adaptation to climate. When we send our consumptive patient out of the city to the country, mountain or plain, seashore or sanatorium, from the casement of a tenement to its roof, or from an area room to the fire escape, we are again recognizing climate. We need more laboratory experimentation to fix these values.

DR. J. O. ROE, of Rochester, N. Y., read a paper on

WHY WE TAKE COLD.

The theory of mechanical congestion of the internal organs by the action of cold on the surface of the body is entirely inadequate because we all know that this form of congestion does not lead to true inflammatory action, since, in an attack of acute coryza, the Schneiderian membrane is so near the surface of the body that the blood should be driven away from it by cold and not into it.

Dr. Roe said that coryza or cold in the head is in fact simply a manifestation of disturbance of the vasomotor centers which is caused by a toxic condition due to uneliminated débris of unassimilated or effete products, which is very commonly termed "lithemia." The toxic effect of the lithemic product on the sympathetic nerve ganglia produces a contraction of the arterioles throughout the body and, consequently, an increased blood pressure. Since, then, the capillaries of the mucous membrane throughout the body receive less support on account of its great vascularity than the capillaries of other parts, they give way under the increased blood pressure with the resulting mucous fluxes from the various surfaces. When the mucous flux, which is nature's method of relieving the engorgement, has accomplished its purpose and the toxins have had time to become eliminated by the necessary fasting, and when the restoration of the cutaneous circulation has taken place, then these overdistended capillaries return to their normal caliber, the discharge ceases and the cold or coryza is cured. Dr. Roe acknowledged the rôle of chilling of the body, improper protection, exposure to drafts, damp air, etc., but he considers colds usually due to a depressed condition of the system, a disturbed equilibrium of the vascular system, diminishing the resistance of the system to external changes, whereas such exposure would have no effect if the subject were in a normal condition. Four special germs are held responsible. The bacillus of Friedländer seems to be nearly always the exciting cause of a nasal cold; in the throat and fauces, the bacillus septus; while in the larynx and bronchi, the micrococcus catarrhalis and the micrococcus paratetragenosus seem to be responsible for the cough and bronchial irritation. The use of autogenous vaccines according to the method of R. W. Allen, of London, was advised. Dr. Roe showed the danger of repeated colds.

DR. HUGH M. KINGHORN, of Saranac Lake, read a paper on

THE EMPLOYMENT OF COLD IN THE TREATMENT OF PULMONARY TUBERCULOSIS.

Dr. Kinghorn does not regard the tuberculin treatment such as to be regarded as the basis of treatment in pulmonary tuberculosis. At present the dietetic-hygienic or fresh-air treatment is the only one of established value. He gave Brehmer and Dettweiler credit for overcoming the prejudice against cold air. Following these came Loomis and Trudeau in the Adirondacks. Hypernutrition is the factor of first importance, and cold air helps to bring it about. Patients in his experience do best in cold weather. It is a popular saying in the Adirondacks that one winter

is worth two summers. The treatment should begin at the same time that the diagnosis is made, and should be carried out rigidly. He stated his belief that the patient should at this time be carefully cautioned against settling up his business affairs before he leaves for the health resort or before he begins treatment. He is now suffering from symptoms of his disease, and this perhaps the most critical time of the whole illness. Many cases are irreparably lost at this time because they try to settle their affairs. This extra tension and anxiety may bring on a hemorrhage, or fever, and either of these may alter a good incipient case to an advanced or acute case within a short time. The patient should, therefore, be put at rest and his arrangements should be made by friends. Nourishment and air are therapeutically on a par. The patient should, if possible, spend his entire life in the open air. He derives benefit from cold air not only when the weather is sunny and dry, but also when it is cloudy and damp and when there is wind and rain. Kinghorn believes that there is no basis for the assertion that cloudy and rainy weather are injurious. Snow and rain should not interfere with the cure, proper shelter being provided. Even a moderate degree of fog is not harmful unless it is saturated with coal dust, as in cities. The temperature of the air is not a factor of such great importance as was once supposed. But he acknowledges that thin-blooded and weak patients feel better in warm climates. Rapid changes of temperature should be guarded against. Dr. Kinghorn discussed the question of clothing and cautioned against producing sweating by too heavy clothing, chest protectors, etc. He advocated a process of hardening by using at the outset a sponge of the chest, arms and back in the morning with cold water. For most patients it is not advisable at first to take a cold tub bath each morning, but to stand and sponge from a basin of cold water. He should then rub dry quickly with a coarse towel. At night the legs should be sprayed. Later on, when the patient is strong, a morning tub may be substituted for the sponging. Breathing exercises were also advised, but these are dangerous while there is sputum.

Dr. Charles L. Minor, of Asheville, N. C., read a paper on

THE EFFECTS OF HEAT AND COLD IN PULMONARY TUBERCULOSIS.

Dr. Minor showed that empiricism precedes scientifically demonstrated principles in therapeutics, and it is easier to record impressions than scientific truths. He instanced the use of cinchona bark by the ignorant Peruvian Indians. He hoped that some day, as a result of the work of meteorologists and climatologists, we shall be able to accurately determine why cold or warm air has the effect on pulmonary invalids which years of experience have shown them to possess. Cold weather has a beneficial influence on pulmonary tuberculosis as compared with hot weather. Dr. Minor referred to the former popularity of southern Italy, Madeira and Mediterranean ports for the consumptive. That body temperature is reduced by cold weather all who have followed the temperature curves of cases of tuberculosis know, and Birch had demonstrated that in India the human body temperatures range distinctly higher than in England; while Brown-Séquard made similar observations on a journey from Mauritius to France. Hot climates are dangerous in all cases attended with high heat production, and this includes tuberculosis. It is a matter of common experience, corroborated by scientific observation, that cold weather, if not too extreme, when it can be depressing, tends to do certain things for the body which chance to be just those which we have found favorable in tuberculosis. It raises appetite, assimilation, oxygen absorption, weight, vigor, resisting power and blood pressure; while it lessens pulse-rate, breath-rate, temperature and decreases skin activity. Of course there are many degrees of cold, and it is hard to say which is the most desirable.

Patients, however, with constitutionally low vitality, especially the aged, require warmer climates; so also patients with the more severe forms of kidney trouble. Chronic rheumatism in a tuberculous patient is an indication for a warmer climate. Bronchitis and laryngitis also require it in some cases.. The essence of the difference between hot and cold weather in their effects upon tuberculosis is that the one is a sedative, the other a tonic and stimulant.

Dr. Charles Fox Gardiner read a paper on

THE THERAPEUTICS OF COLD IN COLORADO.

After sketching the history of the cold-air treatment of tuberculosis and its gradual rise in favor as the method of treating the disease, Dr. Gardiner said that in Colorado they had an exceptional opportunity to compare the effects of warm and cold air. The difference between summer and winter, apart from the actual temperature, is not, perhaps, as marked as in many other health resorts. During both seasons in Colorado, dampness of atmosphere and soil are more nearly the same. There is little snowfall in the average winter, and rarely large areas of snow melting into slush. It almost never rains in winter. Watering carts are used to lay dust during the entire year in several of the cities in Colorado. There are few muggy days, and never any exhausting heat. Both Dr. Solly and the author had patients sleeping out of doors as early as 1884 and before. The colder temperature of winter has several advantages in the treatment of tuberculosis over the warmer air of summer.

Dr. Gardiner states that he has found direct sunlight of much benefit to his patients, provided the weather was cold and they had proper protection for the head, the eyes being shaded from all glare. Cold stimulates the appetite. The temperature of patients in a heated term tends to be higher. Pulmonary hemorrhages are probably more liable to occur in winter; night-sweats in summer. Invalids are generally impressed with the benefit derived from winter weather. The geographical distribution of phthisis shows the benefit derived in tuberculosis by individuals living in dry, cold, elevated regions; also that all races have a more rapid and pernicious form of tuberculosis in damp, warm regions.

DISCUSSION OF PAPERS OF DRS. KINGHORN, ROE, MINOR, GARDINER AND PHILLIPS.

Dr. J. Hilgard Tyndale, of Lincoln, Neb.: I understood Dr. Kinghorn to say that vaccine therapy has not risen to the dignity of being universally accepted. If cold air (hygienic) treatment be the accepted method, is it not a fact that more or less permanent arrest by cold-air treatment is mere self-immunization; that is, that it strengthens the defensive powers in the same way that the use of tuberculin does; that, therefore, the use of tuberculin is surely a method to be pursued, at least to be tried, always suited to the individual case. If it is found suitable, then it is to be pursued at the dosage which suits the individual, or if found unsuitable, then to drop it. If cold-air treatment is based on self-immunization, the same basis applies to the use of tuberculin. In my sanitarium in Lincoln, Neb., we use tuberculin in all suitable cases. Vaccine therapy is made obligatory under our laws for indigent state consumptives, as far as the equipment of the

hospital is concerned, but the patient is in no wise compelled to submit to it.

DR. THOMAS W. HARVEY, of Orange, N. J.: Having progressed slowly in the treatment of pulmonary diseases by the use of cold air from tuberculosis to pneumonia and then on to prolonged bronchitis, I have found that all cases of pulmonary trouble are improved by putting them into cold air. In other words, many of my cases of bronchitis, after they had got through the beginning of their illness, get more and more cold air, and I find that my patients with bronchitis and a lingering cough are improved by stopping my various cough medicines, hypophosphites and other things, and taking them outdoors, or putting them up in a bedroom window or in a room with a lot of windows open; even the little children three and five years old I find improve faster and lose their irritating cough with the treatment of cold air, so I have almost come to the conclusion that even the tuberculosis cases which have improved most by being outdoors are those with bronchitis.

DR. JAY PERKINS, of Providence, R. I.: We have heard so much, or the public has heard so much, of the cold-air treatment that it is being carried to extremes. You people in health resorts may not appreciate that as much as those of us who are outside. But I know that in our cities there are a great many people and physicians who are carrying the cold-air treatment to extremes, and to the extreme that they do not give their patients the treatment that Dr. Kinghorn has mentioned, and that is that the patient should be comfortable. Time and again I have seen patients who have slept out of doors and slept with their windows open by the direction of the physician in attendance, and they followed directions so conscientiously that they have suffered from the cold, and that extreme exposure has done them more harm than good. I never advise a patient to sleep out in winter; in the summer I do advise it. In reference to another thing which has just been mentioned. While I am a firm believer in the fresh-air treatment for bronchitis, I wish to differ a little.

Another thing to which I object is putting patients previously accustomed to warm rooms directly into the cold air of winter. As a result of this Dr. Perkins cited one patient who developed a bronchitis which she has been two years getting over. She left the sanitorium in a very bad condition, and went back home and lived under more reasonable conditions, and is gradually getting better.

DR. W. F. R. PHILLIPS, of Washington, D. C.: These papers have brought up some interesting nuts for us to crack. I do not propose to crack any of them myself, for I confess that they are too hard for my teeth. In Dr. Minor's paper he spoke of cold being a tonic, and cited an instance where anthrax bacilli were not infective when the temperature was lowered. I wondered whether he recalled also the fact that some animals immune to anthrax bacilli could be made susceptible to infection thereby by making them cold; if I recall correctly, the rat and the pigeon are absolutely immune to anthrax when at normal temperature. So here we have something that it would not do to base any very considerable deduction upon.

Another thing Dr. Minor attributed a tonic influence to, that is, he seemed to attribute in his paper some of the improvement noticed in the fresh-air treatment to the effect of cold weather, in increasing the excretion of the carbon dioxide, and to increasing oxygen assimilation; in other words, in metabolism. Dr. Kinghorn insisted that it was necessary in fever cases to keep them absolutely quiet to conserve the metabolism. Why is increased metabolism brought about by cold weather beneficial at one time and apparently increased metabolism by exercise not beneficial at another? So it seems to me that we have several things that are problems for us to consider, and if these papers have done nothing else, they have simply brought this to our attention.

While Dr. Roe was reading his paper and referred to the popular belief that drafts are the occasion of colds, I wondered how often we sat in drafts, got wet feet, and other things, and did not get cold; and whether it was not merely an incident in the catching of cold that when we got it we began to look back to see what we had done in the previous few days that was a little out of the ordinary and pick on that little thing as the real thing that gave us the cold.

DR. HUGH M. KINGHORN, of Saranac Lake, N. Y.: I am a great believer in the value of tuberculin treatment. In fact, I use it a great deal together with the cold-air treatment, but what I meant to say in my paper was this, that while tuberculin treatment is of considerable value in the hands of some physicians, that is, while they get good results from it, yet it is not the basis of the treatment of pulmonary tuberculosis. The fresh-air treatment is *the* treatment, and is the basis of treatment to-day for pulmonary tuberculosis. The tuberculin treatment is merely a help, but the fresh-air treatment is *the* treatment.

With regard to keeping the fevered patients at rest and increasing the metabolism, it is with a view to avoiding any exercise whatever. The quieter you can keep them, the better are your chances of reducing the fever.

DR. C. L. MINOR, of Asheville, N. C.: It is, of course, true that in the present state of our knowledge we can record only impressions on such a subject, though I trust that the work in meteorology of such men as Dr. Phillips will in fifty or one hundred years give us a working basis and make the subject capable of scientific analysis as it is not at present.

Now, as to the doctor's objection, I think he is in error, and he will find that in my paper I have said that extreme cold can be and often is depressing, though we all know by experience that moderate degrees of cold are tonic and bracing. Had Dr. Davaine run the temperature very much lower, Dr. Phillips would have found results in accordance with his ideas.

As to the question of the increase of metabolism when fever is raised, it is, of course, true that at such a time we wish by rest and other means to lessen metabolism as far as possible, as every added cause of oxidation in the body increases fever and its tissue waste; where, on the contrary, there is little or no fever, a rational increase of metabolism is beneficial and graduated exercise invaluable. I make this plain to my patients when explaining to them how to exercise by telling them that as long as their deposits in the bank of health are barely sufficient to meet the needs of their mere living, they cannot afford to weaken their credit in that bank by overdrafts as represented by exercise, but that when by rest, food and quiet they have built up their credit in the bank and have a surplus, then they can afford to spend part of that surplus for something more than the mere necessities of living.

As regards Dr. Kinghorn's paper, I would wish to refer to his discussion of the question of sleeping out. Every good therapeutic measure is apt at first to be overdone, and this is true, I believe, of sleeping out, which is now spoken of as a *sine qua non*. My view is that if every moment of time from breakfast until bedtime is spend outdoors, then the patient can safely and well afford to sleep in a room provided it has at

least two and, better, three, windows, especially if he is still febrile and liable to setbacks. When, however, as is liable to be the case when the patient returns home, he must necessarily spend a good part of his time indoors, then I believe it is essential that he sleep out to square up the difference and to get at night the oxygen he has missed in the day.

Dr. James M. Anders, of Philadelphia, read a paper on

STREET DUST AS A FACTOR IN SPREADING DISEASE; METHODS OF REMOVAL.

He considered, first, the effects of the inhalation of non-infectious street dust and, second, street dust as a vehicle for conveying disease germs, or the influence of infective dust. Dr. Anders classified the various kinds of filth composing street dust, from the excrement of horses, dogs and human beings to soot, plaster and cement. Human expectoration received attention. All this contributes to the dust found in houses in our cities and towns. Nasopharyngeal irritation results, and we can trace to it frontal sinus disease, pharyngitis, tonsillitis, laryngitis, asthma and bronchitis, as well as conjunctivitis, pulmonary congestion and edema. Anthracosis was referred to. The dust caused by automobiles was noted. Dr. Gilman Thomson states that it is no exaggeration to state that nine tenths of the acute inhalation diseases and chronic catarrhal diseases are due chiefly and directly to dirt inhalation. The house fly is a carrier of contagion.

The street cleaning of cities should be entrusted to the Health Department and be conducted on scientific lines. The vacuum or pneumatic method as practiced in Berlin gives the best results. It raises no dust and is more complete. The use of crude oil on the streets, especially those paved with asphalt, is inadvisable. Sprinkling was advocated. Street cleaning should be done at night. Dr. Anders suggested that a committee of the American Climatological Association should be appointed to consider the subject from its hygienic and medical aspects, and to make a report at the next annual meeting. The legitimate scope of this committee should include an appeal to the mayors of all cities requesting them either to appoint special commission or to urge existing bureaus of health to study the problem with special reference to the good results already obtained elsewhere.

DISCUSSION

Dr. J. H. Elliott, of Toronto, Canada: Just a word regarding the use of oil on the streets. The city of Toronto two years ago began the use of oil on the macadam streets, and it will interest those who are here from cities where there are macadam streets to know that our city has adopted the use of oil on all the macadam streets, not only because it is more effectual, but because it is cheaper. It is cheaper to oil a macadam road than it is to water it.

Dr. I. H. Hance, of Lakewood, N. J.: Last year the streets of Lakewood were oiled very largely at a cost not much greater than water. In this connection there was one source of dust that was not mentioned in the paper. It is the handkerchief which is carried around by the ordinary individual; you do not come in contact with it in the street proper, but in the street car, and when some one sitting next to you on the street car pulls out a soiled handkerchief and shakes it out, you may be the victim of infection. I think it is a very serious factor in the spreading of contagion. It would almost seem as if one should get up a society for the use of clean handkerchiefs.

Dr. Thomas Darlington, of New York, N. Y.: There are one or two thoughts that occur to me. They are, first, in regard to smoke. I had the privilege of arresting 243 persons, prominent manufacturers, for smoke coming from their chimneys, and only obtained eight convictions.

In New York City the greater per cent of the dust in the street, about 90%, is due to horse travel, and that, of course, will be largely gotten rid of by means of more motors.

So far as the uncovered foods are concerned, last year I caused over 1,900 people to be arrested and obtained convictions for uncovered food, but there are just as many to-day as before. Making arrests in large cities does not stop the violation of the law.

So far as spitting is concerned, perhaps if the paper of Dr. Anders could be circulated it would do a great deal of good towards educating the people. Women do not spit very largely from the fact that they do not smoke. There was a time when it would have taken half of the people of New York to arrest the other half for spitting. It is a question of educating the people that spitting is not the thing to do. After all, it is the education of the public that is needed.

The question of the removal of dust is a very difficult thing, because many large cities are committed to certain plans and it is almost impossible to have the latest manufacture of any thing, particularly if it is patented; a patented article, as a rule, cannot be bought by the city. But I have very great hope in the future that we can have more education. The same thing is true about the farmer. If he believed that there were germs on his hands or on his pails which, transmitted to children, would cause their death, he would wash his hands, and he would wash his pails.

Dr. N. S. Davis, of Chicago, read a paper entitled

A NEGLECTED FOCUS OF TUBERCULOSIS.

He dealt with prison tuberculosis and stated that each prisoner who is set free with tuberculosis is sure to become a focus from which the disease will spread among his friends and neighbors; further, there is a strong liability that under these circumstances he will relapse into a criminal life. The mortality of prison tuberculosis is very high, about 60% according to Dr. Davis. Jails are commonly infected; ventilation is bad and the prisoners are in a very receptive state. Dr. Ransom's work at Clinton Prison, at Dannemora, N. Y., was quoted and commended. The experience of the farm at Huntsville, Texas, was given and the reduction of mortality at other prisons was noted. By improved methods of dealing with tuberculosis the mortality at Sing Sing, N. Y., was reduced to one fourth; at Auburn, to one ninth, and at Clinton it compares favorably with that at sanatoria where consumptives of all classes are received. In Texas all consumptive prisoners are sent to the farm at Huntsville, and during the first three years of its existence 180 cases were received; the mortality fell off one half.

Dr. Davis made a plea for laws requiring examination of every one arrested and detained in prison more than one or two days, and a re-examination as often as once in six months. Segregation was advocated and more attention to hygiene of the persons and cells of the prisoners. Outdoor treatment was advocated. Early trials were urged and prisoners in an advanced stage should not be pardoned, but cared for by the state.

DISCUSSION.

Dr. E. O. Otis, of Boston, Mass.: To the list of prison sanitariums which Dr. Davis mentions I would add one in Massachusetts. We have a special state

sanitarium for prisoners at Rutland, to which tuberculous prisoners are transferred from the various penitentiaries of the state and treated under similar outdoor conditions as exist in a state sanitarium a short distance away.

DR. J. H. ELLIOTT, of Toronto, Canada: The paper brought up two very important points, the treatment of tuberculous prisoners and the care of prisoners to prevent them becoming infected while serving their sentences. These are two quite different problems and unfortunately the second, which is most important, the prevention of infection, is closely bound to our present jail system. I think that we all recognize that our present system of confinement in jail is one which makes a prisoner a confirmed criminal. But if we take our prisoners out of the jails in which they are confined, usually at manual labor, and move them out into the country on a farm, we shall not only make men of them, but will lessen this mortality due to infection in the prisons. Following the example of some of the cities and states in the United States, our provincial government in Ontario has bought a large farm where they have good water supply, beds of gravel and sand, deposits of rock, particularly limestone rock, and the prisoners are already being transported to this farm and are building roads and putting up buildings. I think we should do all we can to foster this in the different states and provinces, and in this way indirectly to some extent, and also very directly, we shall lessen this mortality.

DR. HENRY MARTYN BRACKEN, of Minneapolis, Minn.: The question of the care of prisoners of penitentiaries is rather a simple matter, but the proper care of those in the jails and workhouses is a difficult proposition. And this is true because the prisoners of penitentiaries, the larger institutions, are under the control of people rather outside of politics, while the jails and workhouses are often under the control of changing supervision, from a medical point of view, and even those who have charge of the medical end take little interest in the sanitary side of it. The transfer of tuberculosis patients to special sanatoria or farms is certainly most desirable, and, where it can be carried out in relation to the larger institutions, is most satisfactory. In Minnesota the proper care of those in the state institutions has been observed carefully for years. The same man, a resident of Stillwater, has been in charge, and I think it must be at least fifteen years ago that there was a division set aside for the care of tuberculosis patients, and they were given special work keeping them outside as far as possible. Special care was taken to disinfect their cells and destroy their clothing and bedding, and in the reconstruction of the new institution a special ward for the tuberculosis prisoners is being provided. The death-rate of that institution from tuberculosis went down very low, then it went up because of the importation of a lot of tubercular prisoners from outside of the state. Then the rate was again reduced. I simply want to emphasize the point that there is a difficulty in taking care of these individuals in the smaller institutions, and the society's attention should be directed to improve the local conditions.

DR. GUY HINSDALE, of Hot Springs, Va.: I read a paper on this subject before the society at our meeting in 1905 and gave an account of an inspection of the Eastern State Penitentiary of Philadelphia, where the segregation of prisoners in solitary confinement has been used for so long. That prison was subject to a very heavy mortality from tuberculosis amounting to two thirds of all deaths. After the report which I made to the Pennsylvania Society for the Prevention of Tuberculosis, and to the inspectors of the prison, it was very thoroughly overhauled and the cells disinfected, and special attention given to the tubercular prisoners by way of giving them better air and exercise and carrying out to some extent the outdoor cure. This resulted in great improvement in the mortality rate of that prison, and under Dr. W. D. Robinson, who was the prison physician for a great many years in Philadelphia, and Dr. W. W. Leach, the resident physician, the hygienic conditions of that prison were immensely improved. Dr. Robinson took the matter up so vigorously that it gave rise to some controversies, but his work is to be thoroughly commended.

It occurs to me that the practice of sending prisoners to the road on the chain gang which is common in our southern states is preferable to putting them in solitary confinement as they do in the Eastern State Penitentiary in Philadelphia.

DR. C. L. MINOR, Asheville, N. C.: One of the difficulties in meeting this problem which I would wish to dwell upon is that we are handling not merely the poor, but the criminal poor, and, in my experience, persons of this class prefer not merely to be dirty, but take a vicious pleasure in soiling and defacing their surroundings, so that you cannot get their co-operation in improving the sanitary condition of prisons. The negro in our Southern jails is very ignorant and very dirty, but rarely malicious, but the scum of Europe, such as Dr. Davis sees in Chicago, can be made to improve their ways only by superior force and by an amount of vigilance which it seems impossible to hope for while, as is the case, politicians run these institutions.

DR. N. S. DAVIS, of Chicago, Ill.: I do not feel pessimistic about it, but to reform jail management, the present method of the care of prisoners must be completely changed. If they are still to be put in small cells which cannot be properly ventilated and cleaned, which are unwholesome in every respect, it is almost impossible to accomplish anything, but I believe this will be changed. I hope that those present will agitate for the needed reforms.

DR. ARNOLD C. KLEBS presented a paper on

SURGICAL TUBERCULOSIS TREATED IN THE HIGH ALPS.

He described the method adopted by Dr. Rollier and Dr. Bernhard. Rollier recently reported on thirty-five patients treated by heliotherapy at high altitude. His experience includes nearly 150 cases of tuberculosis of various locations, exclusive of the lungs, treated by mountain sunlight with excellent results.

DR. ARTHUR K. STONE read a paper on

TUBERCULOUS PERITONITIS; A PLEA FOR THE TREATMENT OF PERITONEAL TUBERCULOSIS BY HYGIENIC RATHER THAN SURGICAL MEASURES.

This paper appeared in the JOURNAL, June 16, 1910.

DISCUSSION.

DR. E. O. OTIS, of Boston, Mass.: Last winter a child about ten years of age was referred to my service in the Tuberculosis Clinic of the Boston Dispensary with a diagnosis of peritoneal tuberculosis. The diagnosis seemed clear. The unusual thing was that the child seemed to be in perfect general condition with rosy cheeks, and apparently suffering no inconvenience. She was put under good hygienic conditions, kept out of doors, and as time went on the ascitic symptoms gradually disappeared and apparently the child was making a rapid recovery. I simply mention this as an instance corroborating what Dr. Stone said.

DR. C. L. MINOR, of Asheville, N. C.: In my practice up to a year or so ago I always advised operation in

peritoneal tuberculosis, and usually have had very satisfactory results, so that I learned to feel a good deal of confidence in the operation. Recently I have had some cases in which I have tried a purely hygienic treatment and have gotten some very satisfatory results.

I believe the difficulty often is that as a good many of these cases have not done well after operation, the doctor feels that he cannot advocate so serious a step. But I believe we owe it to our patients to give them the chance, and that we have enough records of good results by surgery to feel that, after giving medicinal measures a fair trial, we are fully justified in calling in a surgeon, since the danger should not be great and the likelihood of improving the outcome seems to be fair. The operation which I refer to has been a simple opening of the abdomen, an examination of the condition of the parts, which were usually studded with many tubercles, and then sewing up the wound without the use of irrigation, chemicals, etc.

Dr. Elliott: There are two questions on which I would like to have information. First, should we, because of the intestines being involved, give a diet other than that we would ordinarily give in a case where fever and tuberculosis are present?

The other question is while the surgical treatment is acknowledged to have been successfully employed in the wet cases, have we any figures to show us whether the operation is effectual or harmful in the dry cases? I think there is a general belief that in the dry cases surgical interference is harmful.

Dr. Stone: It seems to me that the mere operation of opening and sewing up again is simply the idea of doing something, something that you do not do in the lung cases you are attending, and your lung cases, taken in time, get well. In the abdominal cases you have the idea along with the surgeon that if you do something you cure your patients. We all see our lung cases go along without marked change for a long time and then change quite suddenly for the better, and in some of the abdominal cases that I followed out, patients who were sent home to die, went home and improved; one took up Christian Science and in three weeks was around and down at the beach. Still another went up into a back county of New York and had a physician who gave a pill and the patient immediately got well. And so it has gone in that way.

I do not feel that an operation is altogether a perfectly simple thing. I find that one third of the cases in Massachusetts had ulcers in the wounds afterward. I found in literature that there were cases where bad accidents occurred, as rupture of the intestines.

How long to wait? That is a question that Dr. Gelpke has considered quite extensively, and he states that he would not remove fluid under six weeks, but just more than that I could not state.

Dr. Will H. Swan, of Colorado Springs, Colo.: I think this paper is a very timely one and one of very great value because I think we should not take the position to which all of us have been inclined that tubercular peritonitis is necessarily a surgical disease. At the same time I think there are a certain number of cases where there are symptoms of abdominal pain, digestive disturbances that go on for considerable time, and by and by we get an attack of what is pretty definitely appendicitis, and with operation patients get well of that attack, and they are very much better and many of them relieved of their abdominal symptoms from that time on, and do very much better with the tuberculosis which may be coincident. I believe in many of these cases we have a vague indistinct chronic appendicitis that we have not been able to recognize up to a rather more definite attack to call attention to it. We have had it upon a number of times. I have in mind now two or three cases where I have been trying to get the consent to operate for what I suspect to be occurring, that is, chronic appendicitis, where there has been not marked but vague abdominal symptoms. If the patient is not doing very well, and no apparent reason for it, I wonder if an operation and the removing of the appendix might not be fitting. In regard to diet, I think there is no special change that should be considered, for in these particular cases that I have been trying to discuss, those with the general involvement of the peritoneum, the intestines are not involved. Hemmeter, in 56 autopsies upon patients dying of intestinal tuberculosis, found that in none of them was the peritoneum involved, and in several cases which I have seen where the peritoneum became involved by way of the intestine, it was evidently the colon peritonitis that developed and not a tuberculous one. I cannot state exactly in regard to prognosis of the dry cases as compared with the wet ones where there has been operative interference. I noted that in the Massachusetts General Hospital, on looking up this series of cases, the dry cases, operative and non-operative, gave a better source of statistics than the wet ones as to the permanency of cure. This is at variance with most observers.

We must consider that a certain number of these dry cases probably were wet at some time, and that a certain amount of effusion often occurs, and the patients do not record it. I find that in the history a number of times that patients have stated that their bellies have been swollen at some time, but when they came under the observation of the hospital and the doctor, the abdominal cavity was perfectly dry.

May 4, 1910. Afternoon Session at 2:30 p.m.

Joint session with the Climatological and Otological societies at the New Willard Hotel. General topic for discussion: "Vaccine Therapy."

According to an arrangement suggested by the Executive Committee of the Congress, the Climatological Association invited the Laryngological and Otological Associations to hold a combined meeting on May 4, at which the subject of Vaccine Therapy should be discussed from the standpoint of these three associations. Accordingly the following members prepared papers and took part in the discussion:

American Otological Society: Dr. B. Alexander Randall, Philadelphia, Pa.; Dr. Henry O. Reik, Baltimore, Md.

American Laryngological Association: Dr. J. W. Gleitsmann, New York City; Dr. H. S. Birkett, Montreal, Canada; Dr. F. C. Cobb, Boston, Mass.; Dr. C. G. Coakley, New York City.

American Climatological Association: Dr. Jas. Alexander Miller, New York City; Dr. Herbert M. King, Liberty, N. Y.; Dr. Walter A. Griffin, Sharon, Mass.

(To be continued.)

Book Reviews.

Clinical Commentaries Deduced from the Morphology of the Human Body. By Prof. Achille de Giovanni. Translated from the second Italian edition by John Joseph Eyre, M.R.C.P., L.R.C.S.I., D.P.H. Cambridge. New York: Rebman Company. 1910.

This volume, dedicated to Charcot, presents the results of the author's critical studies in anthropometry and his exposition of the theory, more familiarly associated with the name of Bertillon, of human individuality based on and determined by measurements. Generalizing from this, De Giovanni undertakes to bridge the gap between morphology and pathogenesis by deducing from his anthropometric observations certain "combinations," types or categories, each characterized by peculiar pathologic susceptibilities. These types, which amount to little more than a rehabilitation of the old diatheses on morphologic instead of empiric grounds, represent classes to which individuals may by their measurements be conveniently referred. This ingenious theorem seems rather a curious example of Latin rationalism than a contribution of particular value to clinical medicine.

Physical Examination and Diagnostic Anatomy. By CHARLES B. SLADE, M.D., Instructor in Physical Diagnosis, University and Bellevue Hospital Medical College, New York. 12mo. Pp. 146. Illustrated. Philadelphia and London: W. B. Saunders Company. 1910.

A small, succinct and well-arranged book on any subject in medicine is welcome in these days of somewhat ponderous treatises. In this volume of 146 pages, including a full index, is contained the fundamental methods and principles of physical examination, well illustrated largely by line drawings. As an outline of a large subject the book is to be strongly commended. It aims to be practical and makes merely the modest claim of being a preparation for more comprehensive works. It is admirably printed, with a judicious use of italics and heavy-faced type for paragraph headings.

Chemical and Microscopical Diagnosis. By FRANCIS CARTER WOOD, M.D. Second edition. New York and London: D. Appleton & Co. 1909.

The work is divided in nine parts, as follows: Blood, gastric contents, feces, parasites, oral and nasal secretions, sputum, urine, exudates and transudates and milk. It will be seen at a glance that all the branches of clinical laboratory technic are covered in such a category, and careful scrutiny of the various chapters will disclose them to be as complete as is necessary for use by student, teacher or practitioner. Schmidt's method for the examination of intestinal contents is a useful addition to an American textbook. The progress of medical research requires especial notice to be taken of the Wassermann reaction, the opsonic index and the tuberculin reaction. This new edition maintains the high reputation achieved by the book in its original form. It is scientific, yet eminently practical, and a credit to American medicine. In fact, no better work on laboratory diagnosis has been published in any language. The text is illustrated by many excellent colored plates, photographs and drawings.

The Harvey Lectures. Delivered under the auspices of the Harvey Society of New York, 1908–09. By Professors A. CALMETTE, W. G. MACCALLUM, GRAHAM LUSK, W. FALTA, M. J. ROSENAU, A. B. MACALLUM, J. B. LEATHES, PHILIP HANSON HISS, JR., and Doctors JOHN F. ANDERSON and C. B. DAVENPORT. Philadelphia and London: J. B. Lippincott Company. 1910.

Few American scientific publications comprise within so small compass the names of so many distinguished authorities as those of the Harvey Society. This fourth series of lectures, as the editor suggests in his preface, furnishes "a striking example of the many points of contact between medicine and the collateral sciences." Probably the subjects most likely to attract general interest are "Intestinal Infection and Immunity in Tuberculosis," "Fever," "Anaphylaxis," "Problems in Immunity," and "Heredity in Man." Though their treatment is in no sense popular, these and the other essays which compose the volume should appeal not only to physicians, but to other intelligent readers, for they deal with scientific problems of actual importance in the human life of the day.

Hand-Book of Electro-Therapeutics. By WILLIAM JAMES DUGAN, M.D. With 91 illustrations. Philadelphia: F. A. Davis Company. 1910.

Treatment by some form of electricity has been, and promises long still to be, one of the strongest trump-cards of the medical charlatan. The present volume undertakes to describe the legitimate uses of electricity in medicine, the methods of its application and the indications and contra-indications of its employment. It is clearly written and well illustrated and should prove a valuable manual of a department of therapeutics little understood or utilized by the average physician. For the therapeutic and diagnostic uses of the x-ray, the reader is referred to special treatises on that subject.

Chirurgische Operationslehre für Studierende und Aerzte. Von Prof. Dr. FRIEDRICH PELS-LEUSDEN, Oberarzt der chirurgischen Universitätsklinik und Leiter der chirurgischen Universitätspoliklinik an der Königlichen Charite zu Berlin. Mit 668 Abbildungen. Berlin and Vienna: Urban & Schwarzenberg. 1910.

This well-printed volume of seven hundred and twenty-eight pages appears without a binding, undoubtedly a mistake for a book which is aimed to find a circulation in this country. Moreover, it is uncut, and so doubly unapproachable. The volume has many extremely good points. It deals with surgical therapeutics only and is brilliantly illustrated with most informing diagrammatic cuts. Excellent operations are chosen for description, and are related with the usual German dreariness. Nevertheless the book is so admirable a compendium of the best modern practice that we doubt not it will find a place in all reference libraries.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, NOVEMBER 10, 1910

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 Tremont Street, Boston, Mass.

SOME BIOLOGIC ASPECTS OF CANCER.

From *Biometrika*, "a journal for the statistical study of biologic problems," we have received an interesting reprint of "a statistical study in cancer death-rates" by G. D. Maynard, F.R.C. S.E., of Pretoria. At a time when the increasing death-rate from cancer in our own country and among other civilized nations is becoming matter of so much medical moment, such a study is of particular value. Dr. Maynard presents a very extensive and profoundly mathematical investigation of the relations between cancer and a large number of attendant conditions, such as race, age, sex, occupation, climate, social status and other diseases, notable diabetes and insanity.

His work is based principally on statistics from the United States, but includes also figures from other countries. His conclusions are striking and deserve serious consideration. He finds that his statistics give no support to the suggestion that cancer is of infectious origin. He finds that correlations exist between cancer, diabetes and insanity, and believes that these are not fortuitous. He suggests that "conditions of modern life, acting on physiologically unsound material, may account for the correlations between these three diseases, as well as for their increasing rates." The remedy for this condition he finds in eugenics.

In other words, Dr. Maynard regards cancer as a disease of the unfit, and includes diabetes and insanity in the same category. True, all are in a sense cellular perversions, morphologic or functional. Yet the prospect in face of this grim trilogy is perhaps not so gloomy as might appear. For the question rises whether a person has cancer because he is unfit, or becomes unfit because he has cancer. If the former, then the situation is fatalistic enough; but if the latter, there is at least a reasonable prospect that if we could but rid him of his cancer he would again become as fit as the man who has successfully recovered from yellow fever, or a hare lip, or a broken leg, or appendicitis. At a time when the laboratory study of cancer seems to offer such high hopes that we may be able ultimately to solve its riddle, such conclusions as Dr. Maynard's should in no sense act as a deterrent from its further pursuit. Cancer well deserves its name "malignant," but, far from being considered a biologic stigma, should for the present certainly be regarded as a definite extraneous scourge to be grappled with and conquered by more tangible means than eugenics.

THE HOSPITAL SCHOOL FOR TUBERCULOUS CHILDREN AT FRANKLIN PARK.

Mr. Price, secretary of the board of the Consumptives' Hospital trustees, in the daily papers has defended the action of the majority of the board of the trustees (Messrs. McSweeney, O'Brien, Price and Mrs. O'Callahan), as the Boston *Journal* says, in voting to close the Hospital School at Franklin Park. The defense practically amounted to saying that as only a few children were being cared for, and as there were many more who probably had tuberculosis that could not be cared for, therefore this form of hospital work should cease. But this argument, carried out to its logical conclusion, would stop all the work of other departments of the tuberculosis hospital and put an end, if applied, to every form of hospital philanthropy, for never can we have provision made for all the sick of the city. The other argument, that the children, being school children, should not be fed, is also entirely beside the point. The children were tuberculous children needing care and were sent to this department of the hospital. Here they were allowed to attend school a part of the day as a therapeutic measure, and, as another part of the cure, were properly fed and kept in the open air. They were patients in a hospital, not scholars in a school.

The care of persons having tuberculosis in "day camps," whence they return to their homes at night, is a well-recognized method of arresting the progress of tuberculosis. Dr. Floyd, physician to out-patients at the Consumptives' Hospital, has had much experience in the conduct, since 1906, of such a "day-camp" at the House of the Good Samaritan. The statistics of his work

there in a period of several years will compare favorably with those of the average sanatorium. In all "day-camps," rest, fresh air, and good food, supervision in the homes, are the methods used to bring about favorable results. Patients with any form of tuberculosis must be fed, and among them, children, as well as any other unfortunates.

Physicians and interested laymen as well should hold these following simple facts regarding the Hospital School in mind. The Boston Association for the Relief and Control of Tuberculosis conducted a "day-camp" for tuberculous children during the summer of 1908. This was successful, and at the beginning of the school year the school board consented to furnish a teacher, who held a "district school" at the "camp." In this way the parents were persuaded to allow their improved but still really tuberculous children to continue in their outdoor life, for parents and children alike believe that school should be attended at all costs if the child is not distinctly sick. Later in the year the "camp" with the school attachment was moved, thanks to the Park Commission, to the roof of the refectory building at Franklin Park. These children, under the care of the physicians of the association, with the help of the teachers to maintain order and give employment to their busy brains, and the help of the nurse who followed them to their homes, and all under the wise direction of Miss Isabel Hyams, did exceedingly well, and at the end of the school year the experiment was pronounced by all who investigated or were connected with it as a success.

During the summer of 1909, some of the children went to the new land of the association, called Prendergast Camp, where they were looked after by a young man as teacher, taught in gardening and other nature studies, and amused, fed and kept in the open. Later the board of trustees of the Consumptives' Hospital voted to take over this work and thus to establish a department for children at the same place in Franklin Park. Provision was made for the care of one hundred children.

The board of trustees of the Boston Consumptives' Hospital had decided to build suitable hospital wards for the care of really advanced cases of tuberculosis. Plans had been drawn and the buildings were in the process of erection. An out-patient or dispensary department had been started, by means of which, and the co-operation of other hospitals in the city, it was hoped that a large amount of definite knowledge regarding the distribution of tuberculosis in the city of Boston would be acquired. A "day-camp" for adults which had been successfully conducted by the association was taken over. This was in the very beginning, and a number of patients were temporarily cared for while hospital accommodations were being prepared. This form of the hospital work will probably decrease in amount, though it will and should always have a place in the workings of a hospital department for the control of tuberculosis. The plans for the care of the adult case having been developed and slowly approaching completion, it seemed wise to take the next step and see what could be accomplished for the children.

As yet the world has done but little for the child with pulmonary tuberculosis. Unless the child is very sick or confined in bed it is hard to convince parents, teachers and even intelligent lay workers and some physicians that the child is dangerously ill. The public has not yet arrived at the place in its education in tuberculosis where it would recognize the need of placing such a child in a hospital even if there were such a place provided to send him. Such a children's department of a hospital as ours in Boston for the care of tuberculous patients should be provided. The school committee will have to co-operate in order that the best methods that we know of for enforcing rest and order can be carried out. Even after a children's ward has been built, there will always be a number of children who can best be cared for by the camp plan, the child thus remaining with the parents and becoming a constant source of hygienic information to the family,—an educational factor of great importance. The best way in which education of the community can be advanced will be along the line of the Boston hospital school. Here the children who are found by the school physicians and others to be definitely tuberculous, even when they are not so to be recognized by the laity, can be sent and put under the charge of competent physicians and nurses and given, with proper food and clothing, the best possible chance for their recovery. To accomplish this, the school side, which is really a therapeutic measure, will have to be emphasized and put to the front, because it is the school that the parent recognizes, while the real object is to get the child under hospital treatment. It is distinctly a hospital problem, not a school problem.

The questions at issue regarding the hospital school have been much obscured by the fact that it has been called an "open-air school," while the other fact, that was perfectly obvious to all the founders of the plan, that it was a method of caring

for tuberculous children, has been forgotten or disregarded. It is perfectly true that applications of methods used in this hospital school can be adapted to general school work for *non*-tuberculous children. But all the conclusions thus far have been based on the work done for the arrest of real tuberculous processes in the children that have been under the charge of the hospital trustees. That the trustees of the Consumptives' Hospital do not see their way to provide for all the children whom the physicians in the city send to them is no more reason for closing their hospital school than for closing the rest of their hospital because they have not beds for all the tuberculous patients of Boston. Let them do what they can, run their hospital school to the limit of its capacity, and not make preparations to close it at the end of the present fiscal year.

THE ECONOMIC COST OF DISEASES.

The concept of disease as a form of economic waste, though not exactly new, is rather likely to appeal to a good many Americans as a motive for efforts at its prevention. It is significant that, at a meeting of the Boston Chamber of Commerce last week, this aspect of disease was taken under special consideration, and reports on various topics of the question were presented by members of the Chamber of Commerce committee on public health and preventive medicine. Dr. Richard C. Cabot, the chairman of this committee, presented some figures representing the estimated pecuniary cost of the incidental ailments of life to the people of our community. There are in Boston approximately 150,000 wage-earners, receiving an average wage of $700 a year. If each of them loses twelve days, or two working weeks, a year from sickness, that loss represents to each of them $28, or a total of $4,200,000, besides a loss of 6,000 years of time. Moreover, the experience of certain large corporations has demonstrated that it actually pays in dollars and cents for the owners of mills, factories and workshops to make some provision for caring for the health of their employees. This may be done in various ways: by the employment of a graduate nurse as resident in such buildings, to supervise the hygiene and habits of employees, and by the establishment of "shop clinics" administered by properly qualified and paid physicians.

Propositions of this sort were presented and discussed at the meeting of the Chamber of Commerce by Dr. Cabot, Dr. L. R. G. Crandon, Dr. Horace D. Arnold and Mr. Stanley King. No definite action was taken, but it was evident that many of the ideas suggested were novel and appealed strongly to those present. The progress of preventive medicine is slow, when its motives are purely humanitarian; it will become more rapid when it is recognized by large classes in our society as the best means towards health as a business asset.

INCREASE OF BIRTHS IN FRANCE.

Official report from Paris states that during the first six months of the year 1910 the births in France exceeded the deaths by 21,189. This information has excited great satisfaction in France, where it is regarded as evidence of the cessation of the menacing decline in population with which that country is confronted.

At first glance the figures seem impressive, but as a matter of fact they probably represent only a temporary fluctuation, a gain that is trivial in itself and likely soon to be more than counterbalanced. Moreover, no adequate reason is assignable for such increase, since it is too soon for the taxation of bachelors and the provision of increased salary for government employees to have affected the birth-rate. Meantime the rate in Germany continues at 36 per thousand, in Austria 37, and in Hungary 40. It is to be feared that in France there is no immediate prospect of any such fecundity as is shown by her Teutonic and Magyar neighbors. Her brief increase is transitory and fallacious.

NEW THERAPEUTIC USE OF FORMALIN.

In the August number of the *American Journal of Orthopedic Surgery* is an article by Dr. Roland O. Meisenbach, of Buffalo, N. Y., presenting the results of some interesting and delicate animal experimentation performed with a view to determining the effects of chemical and mechanical stimulation upon bone-growth. A series of injections of various irritating substances was made in the region of the upper epiphyseal line of the tibia in young rabbits. The lesions thus formed were then studied by x-ray and microscope at varying intervals of time, with the result that the stimulated bone was found to ossify more rapidly than normal bone. Mechanical stimulation appeared to affect chiefly perichondral bone-formation, whereas chemical stimulation affected chiefly endochondral bone-formation. Of all the substances experimentally employed for injection, formalin proved most satisfactory, since it com-

bines the effects of mechanical and of chemical stimulation, causing the "formation of osteogenetic tissue by influencing the zones of provisional calcification and calcified matrix, and by increasing the number of osteoblasts derived from the perichondrium." The author believes that his observations suggest a possible new therapeutic use of formalin by injection to stimulate bone-growth in congenital shortening of a limb, in infantile paralysis, bone-tuberculosis, osteomyelitis, obstinate non-union of fractures. If verified by clinical application, the results of his admirable piece of research seem likely to be the suggestion of a new therapeutic procedure that may prove of great value in general as well as in orthopedic surgery.

MEDICAL NOTES.

A CENTENARIAN. — Mrs. Hela Hurd Cook, who died last week at Clayton, N. Y., was locally reputed to have been born in 1808. Her father fought in the American Revolutionary War.

THE HARBEN LECTURES. — The Harben Lectures of the Royal Institute of Public Health of London for 1912 will be given by Dr. Simon Flexner, of the Rockefeller Institute for Medical Research, New York.

YELLOW FEVER AT HONOLULU. — Report from Honolulu, Hawaii, states that a case of yellow fever, said to be the first ever known at that port, was discovered on Oct. 30, aboard the Japanese steamer *Hong Kong Maru*, just arrived from Manzanillo, Mexico. The patient has been isolated and the ship duly quarantined.

POLIOMYELITIS IN KANSAS AND IN NEW JERSEY. — Report from Topeka, Kan., states that acute poliomyelitis is still epidemic in that state, where there are said to be at present about one hundred and fifty cases of the disease. At Princeton, N. J., a student in the university died of poliomyelitis on Oct. 29, his death being the second that has occurred there from this infection during the past three weeks.

SOME RECENT CHARITABLE BEQUESTS. — Among other charitable bequests, the will of the late Margaret W. Frothingham, of Cambridge, Mass., allowed last week before the Middlesex Probate Court, makes legacies of $1,000 to the Cambridge Hospital and $500 to the Kindergarten for the Blind, Jamaica Plain.

The will of the late James C. Jordan, of San Francisco, Cal., recommends, although it does not bind, his widow and executrix to present to the Massachusetts General Hospital the sum of $5,000 to be used in such manner as she and the administrator of the hospital may decide.

TWO ACTIVE LIVING CENTENARIANS. — Mr. Charles Beaulieu, of Salem, Mass., is said to have been born on Nov. 3, 1810, in Canada. He was one of a family of fifteen children, and was brought up on a farm. He married in 1836, and had thirteen children, of whom nine are now living. He has always been a hard worker, has lived much out of doors, and still walks a great deal. To these habits he attributes his longevity and present vigorous good health.

Mr. O. M. Ziebach, alleged to be one hundred and seven years of age, was arrested and imprisoned on Nov. 1, at Fort Totten, Grand Forks, N. D., on a charge of introducing spirituous liquor into an Indian reservation. He is said to be the oldest man ever placed under arrest in the United States. It seems unfortunate that such venerable years should not have induced in him greater propriety and sobriety of conduct.

TESTIMONIAL DINNER TO Dr. J. M. BODINE. — For forty-five years Dr. James Morrison Bodine, as Dean and President of the Faculty, has presided over the destinies of the University of Louisville Medical Department. Now entering his eightieth year he continues to devote his energies to the cause of medical education. His many friends and pupils scattered throughout the country have deemed this an appropriate occasion to show their appreciation of his devotion and their affection for him personally.

To this end it has been decided to give him a testimonial dinner on Dec. 16, 1910, at the Seelbach Hotel in Louisville. Those friends whom the committee has been unable to reach by invitation are cordially invited to attend and are requested to signify such intention at once by writing to the chairman of the committee.

CHOLERA IN ITALY. — During the week ending Nov. 5, 63 new cases and 28 deaths of Asiatic cholera are reported to have occurred in Italy, showing a slight increase over the previous week. It must be remembered, however, that these figures are probably not entirely accurate or reliable. In a report recently made at Rome by the Italian national board of health, it is stated that much of the diffusion of the disease has been due to defects in the water supply of Apulia. It is expected that a measure will be introduced

into the Italian parliament authorizing the immediate construction of improved works, dams, aqueducts and wells in the effort to provide better supply for this district, and appropriating for the purpose an amount equivalent to $60,000,000.

More Milk Convictions. — Two milk dealers of Everett, Mass., were last week fined $15 each before the Malden District Court for having in their possession, for sale, milk not up to the standard required by law.

Before the United States District Court at Concord, N. H., on Nov. 1, eleven milk producers of that state were fined $10 each for violation of the pure food law in shipping to Boston, for sale, "milk containing deleterious or putrid matter." The interests and safety of consumers in this city are dependent on the responsibility and conscientious zeal of public officials outside as well as within Massachusetts.

Punishment for Refusing Vaccination. — Last week, it is stated, about three hundred and fifty students and several instructors in the University of Minnesota, at Minneapolis, refused to be vaccinated after exposure to a case of smallpox which occurred in the vicinity. For this infraction of state law, which provides compulsory vaccination under such circumstances, all recalcitrants were quarantined in their rooms and forbidden to take any part in college exercises for three weeks. It is to be hoped that this wise and condign punishment will prove of value not only as a disciplinary measure, but as a check to the growth of the so-called "anti-vaccination sentiment," whose spread threatens danger to the community as well as to the individuals by whom it is entertained.

Decrease of Population in Iowa and Vermont. — Figures from the recent United States census are not yet complete, and until they are there is little profit in speculation upon them. Most important should be the figures representing relative growth in number of native and alien inhabitants. Apparently only two states in the Union have shown an actual decline in population, — Iowa and Vermont. In the former case, it is accounted for by migration to the Canadian Northwest; in the latter, partly by the drain of the Civil War, partly by migration to Boston. The data which give comparative birth-rates remain yet to be worked out. Upon them will rest our classification with the French or with the English in the matter of racial fertility.

Convention of Military Surgeons. — The nineteenth annual convention of the National Association of Military Surgeons of the United States was held last week in Richmond, Va. For the first time in the history of the association, the sessions were attended by representatives from several foreign countries, among them Great Britain, France, Germany, China, Canada, Mexico and Guatemala. At the meetings were discussed various topics relating to the health of soldiers in the regular army and in the national guard, and of sailors and marines. The last day of the convention, Nov. 4, was devoted to subjects connected with the work of the United States Public Health and Marine-Hospital Service. It was voted that the next meeting of the association be held at Milwaukee, Wis.

Railroad Casualties in the United States. — The risk of railroad travel in the United States is illustrated by statistics from a recent bulletin of the Interstate Commerce Commission. In the year ending June 30, 1910, 82,374 persons were injured and 3,804 killed in railroad accidents in this country, an increase of 18,454 injured and 1,013 killed over the preceding year. That these figures are relatively much higher than the corresponding figures in Great Britain illustrates admirably the reckless carelessness and the cautious stability of the respective peoples. Railoads furnish not only much of the romance, but a considerable proportion of the surgical trauma of modern life, among both employees and passengers. Much of this waste of life and health would be as preventable as many of the infectious diseases by intelligent care.

American Public Health Association. — The American Public Health Association, comprising the United States of America, the Dominion of Canada, the Republic of Mexico and the Republic of Cuba, will hold its 1911 meeting in Havana, Cuba, from Dec. 4 to 9. The prospect of having the Association again in Havana has aroused the warmest interest among the physicians there, the secretary of sanitation, Dr. Varona, being particularly interested. The Academy of Medicine has offered its building for the general section meetings. The Hotel Sevilla will be the headquarters of the association. A few years ago a meeting in Havana would probably have discussed yellow fever. The changed situation in Cuba with respect to that disease is shown by the fact that yellow fever has been so completely extinguished on the island that

the local physicians desire rather that tuberculosis be given the most prominent place. The question of the milk supply will also be considered.

It is hoped that at this meeting the recently organized Sociological Section, and the Section on Sanitary Engineering, which was tentatively authorized by the Milwaukee meeting, may be put upon substantial foundations.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.— For the week ending at noon, Nov. 8, 1910, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 50, scarlatina 26, typhoid fever 29, measles 8, smallpox 0, tuberculosis 54.

The death-rate of the reported deaths for the week ending Nov. 8, 1910, was 13.90.

BOSTON MORTALITY STATISTICS.—The total number of deaths reported to the Board of Health for the week ending Saturday, noon, Oct. 15, 1910, was 205, against 181 the corresponding week of last year, showing an increase of 24 deaths, and making the death-rate for the week, 15.94. Of this number 109 were males and 96 were females; 200 were white and 5 colored; 138 were born in the United States, 64 in foreign countries and 3 unknown; 51 were of American parentage, 126 of foreign parentage and 28 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 33 cases and 3 deaths; scarlatina, 9 cases and 0 deaths; typhoid fever, 30 cases and 2 deaths; measles, 4 cases and 0 deaths; tuberculosis, 42 cases and 22 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 25, whooping cough 2, heart disease 31, bronchitis 3. There were 16 deaths from violent causes. The number of children who died under one year was 50; the number under five years, 64. The number of persons who died over sixty years of age was 46. The deaths in public institutions were 83. Anterior poliomyelitis, 1 case and 1 death.

Of the above infectious diseases the following were non-residents: Consumption, 3 cases and 5 deaths. Scarlet fever, 1 case. Typhoid fever, 1 case.

Deducting deaths of non-residents, the total is 174 and the death-rate is then 13.53.

RECEPTION AT THE FREE HOSPITAL FOR WOMEN. — On Nov. 3, a reception, to which we made reference in last week's issue of the JOURNAL, was held at the Free Hospital for Women, Brookline. Tea was served in the afternoon and all the wards of the hospital were opened for inspection by visitors.

SALE FOR ST. MONICA'S HOME. — The annual sale for the benefit of St. Monica's Home, Roxbury, is to be held to-day, Nov. 10, at Trinity Parish Hall, on Clarendon Street.

THE DOCTOR'S DILEMMA AGAIN. — In last week's issue of the JOURNAL we referred to an address by Dr. Richard C. Cabot on "The Doctor's Dilemma." Since that time Dr. Arthur W. Fairbanks, of Boston, in a letter to the public press, has taken issue with Dr. Cabot and expresses his belief that the growth of hospitals in no way menaces the existence of private physicians.

DONATION DAY AT CULLIS HOME. — On Tuesday of this week, Nov. 8, was held the annual Donation Day of the Ladies' Auxiliary of the Cullis Consumptives' Home, Dorchester. The administration rooms of the home were open throughout the day for the sale of articles contributed by friends of the institution. It is expected that a considerable sum of money has been realized from this sale.

FAIR FOR THE BROOKLINE DAY NURSERY. — On Friday, Nov. 11, to-morrow, a fair will be held by the managers of the Brookline Day Nursery, at the Nursery Building, for the benefit of the institution. The fair will be open from 10 A.M. to 6 P.M., and luncheon and tea will be served at appropriate hours. The Nursery has now been established nearly fifteen years, and its work is steadily increasing.

HIGH DEATH-RATE IN FALL RIVER. — In the issue of the JOURNAL for Oct. 27 we published a note stating that in 1909 the city of Fall River, Mass., had the second highest death-rate of cities with a population of one hundred thousand or over in the United States. This statement, which was also made in the public press, was questioned by the Fall River Board of Health. The matter has been investigated by the director of the census bureau of the Department of Commerce and Labor at Washington, D. C., and in a bulletin just issued he reiterates and confirms the original figure, 19.1. This high rate he believes due largely to the excessive infant mortality. In Fall River in 1909 the mortality of infants under one year was 39% and that of children under five years 50% of the total mortality, a proportion "greater

than that of any other large city in the United States, and nearly as great as that of the Filipino population of Manila, which was 64.9% for 1909."

NEW YORK.

Bequests.—Among the charitable bequests in the will of the late Isaac Smith Remsen, president of the I. S. Remsen Manufacturing Company of Brooklyn, is one of $5,000 to the Eastern District Hospital and Dispensary, Brooklyn.

A Low Death-Rate. — It is gratifying to note that the death-rate in the city in the month of October was one of the lowest, if not actually the lowest, ever recorded for a month. It was 13.90, as against 14.48 in September and 15.26 in October, 1909. The corrected death-rate, excluding non-residents and infants under one week old, was 13.03. Among the diseases in which there was a diminished fatality were the following: The weekly average of deaths from measles declined from 7 in September to 2.5 in October; the weekly average from scarlet fever from 3.75 to 2.75; from pulmonary tuberculosis, from 159 to 154.5; from acute bronchitis, from 14 to 11.25; from bronchopneumonia, from 67.25 to 63; from diarrheal diseases, from 190.75 to 146; from diarrheals in children under five years of age, from 181.5 to 138; and from cirrhosis of the liver, from 23.25 to 18. Among the diseases which showed an augmented mortality were the following: The weekly average of deaths from typhoid fever increased from 15.25 to 19; from diphtheria and croup, from 13.5 to 16; from pneumonia, from 46.5 to 67; from cancer, from 74 to 75; from apoplexy and softening of the brain, from 18.75 to 23.75; from organic heart diseases, from 108.75 to 110; and from appendicitis and typhlitis, from 9 to 15. While there is some increase in the deaths from typhoid fever over September, it is noticeable that the mortality from this cause in the city of New York is now less than at the same period last year.

Endowment, New York Foundation.—The bequest of $1,000,000 left by the will of Louis A. Heinsheimer to six Jewish charitable institutions, among which were the Mount Sinai Hospital and the Montefiore Home and Hospital, on condition of their uniting in a single federation, having reverted, in consequence of their refusal so to federate, to the testator's brother, Alfred M. Heinsheimer, the latter has now devoted the full amount of the bequest to the endowment of a new organization which he has founded. This has been chartered under the laws of the state of New York to promote charitable, educational and philanthropic enterprises, and is to be known as the New York Foundation. It will be absolutely non-sectarian in character, and the income of the foundation is to be expended preferably in co-operation with established institutions. Applications for appropriations can be made by the officials of any charitable or philanthropic institution or society, and these will be granted as far as possible in such cases as meet with the approval of the trustees. The president of the Board of Trustees is Dr. Morris Loeb, and the treasurer, Isaac N. Seligman, who is also treasurer of the St. John's Guild.

8. Dlugasch, L. *Exophthalmic Goiter Simulating Typhoid Fever.*

4. Schwartz reports a case of typhoid meningitis in a boy of eight. Two weeks before he entered the hospital he began to have headache and abdominal pain, soon followed by a troublesome diarrhea and vomiting. Three days before admission he took to bed. On admission he was mentally dull; temperature, 101°, soon rising to 105°; pulse, 102; respirations, 36. Spleen palpable. Physical examination otherwise negative. No rose spots. Widal negative. The first meningeal symptom was noticed on the sixteenth day of the disease — a slight Kernig, soon followed by inequality of the pupils. Whites, 10,000; 72% polymorphonuclears. Two days later meningitic symptoms were more marked. Whites, 24,400; 68% polynuclears. Harsh breath sounds and moist râles at right base, posterior. Next day, coma and relaxation of the sphincters; temperatures, 101.5°; pulse, 144; respirations, 56. The diagnosis of tuberculous meningitis was made and lumbar puncture done. Twenty-five cubic centimeters of somewhat turbid fluid under great pressure were obtained. Death followed a few hours later. Examination of the spinal fluid showed cellular elements in excess with a predominance of small lymphocytes. Smear showed many Gram-negative bacilli, no cocci. B. typhosus was obtained in pure culture.

The writer reviews the literature of typhoid meningitis and insists that cases cannot be considered proven where contamination of the cerebrospinal fluid from admixture of blood is not eliminated. This is an essential precaution because typhoid bacilli are present in the circulating blood in practically all cases of typhoid fever. [L. D. C.]

7. Eggleston reports on some clinical experiments with stomach cases. He finds that there may be marked variations in the composition of gastric juice secreted under the stimulus of the same food. These variations may be due to psychic influences. The inhibitory effect of iced food or drink on gastric secretion is slight. Foods containing free fats in any quantity, whether frozen or at ordinary temperature, have a decided inhibitory effect. Gastric secretion is markedly increased by fruit juices, cold or warm. Compound tincture of gentian seems to have but little effect as a gastric stimulant. [L. D. C.]

4. Levy claims that tuberculosis of the tonsils occurs more frequently than previously recognized, owing to newer methods of investigation. Clinically, tuberculosis of the pharynx with or without tonsillar involvement is among the rarer manifestations of tuberculosis. Clinical tuberculosis of the tonsils and that determined by histological examination present marked differences. There is absence of symptoms in the latter and definite subjective and objective manifestations in the former. The diagnosis of true tuberculosis of the tonsils is more satisfactory when based on both clinical and histologic findings. The clinical form is a very grave condition and is probably not curable. Extirpation of the tonsil is rarely indicated in tonsillar tuberculosis.

9. Tyzzer states that the hereditary influence in cancer is shown in regard to species by the frequency of mammary cancer in mice, while they are rare in cattle, which, however, frequently develop primary tumors of the liver and adrenal. Although much of the evidence collected tends to indicate that heredity is not an important factor in the development of cancer, it would appear that this question cannot be definitely settled without more accurate methods than have been hitherto employed. The importance of experimental breeding of animals cannot be overestimated for this work.

12. Carrel and Burrows, in their second article, report the successful growth of sarcomatous tissue outside of the body, even to the cultivation of a second generation. These grow luxuriantly. This work may open new fields for the study of cancer also. [E. H. R.]

2. Hutchison, discussing congenital pyloric stenosis and its treatment, is of the opinion that all cases should be treated medically at first. He finds it very hard to decide which cases should be treated medically and which surgically; he believes a period of medical treatment alone can decide this, but that it should not be carried on too long if there is no improvement and the child's strength exhausted before handing the case over to the surgeon.

15. Wilkinson repeats his previously expressed views in enthusiastic praise of tuberculin as a most potent agent in the cure of all forms of pulmonary tuberculosis. He believes that in the majority of cases the sanatorium only partially finishes its work, discharging patients not cured who soon relapse. According to him, tuberculin is a much more important factor. Sahli, of Berlin, corroborates his remarks; others do not agree in regard to what he calls the failure of the sanatorium. R. W. Philip, in discussing both points of view, presents a sane and moderate statement of this question. [J. B. H.]

13. Weber, A. *An Automatic Apparatus for Developing X-Ray Plates.*

1. v. Bergmann reviews the experimental work on pancreatitis and gives additional experimental evidence in favor of his theory of its origin. He then reiterates his conclusions, namely, that by autolysis of the pancreas a deadly poison may be produced both in man and in animals; that this autolysis may take place either when the pancreas is *in situ* or when a piece of sufficient size has been placed free in the peritoneal cavity; that a fatal poisoning may also be produced by the pancreatic juice of the same or of another animal or by commercial preparation of trypsin; that protection against this poisoning may be developed by preparatory injection of preparations of trypsin; but that neither trypsin nor steapsin of themselves cause the poisoning.

4. Blum describes his technic of epidural injection and recommends it for certain obstinate forms of sciatica and for a variety of other conditions. He says it is more effective than perineural injection, almost painless and free from danger. The canula is inserted through the lower sacral foramen and carried up several centimeters into the sacral canal but high enough to enter the dural sac.

12. The writer states that in severe cases of Basedow's disease hyperplasia of the thymus, lymph glands, spleen, and of lymphatic tissue in the thyroid and bone marrow may be observed, and that as a terminal condition there may be a severe toxic nephritis with necrosis of epithelium. [G. C. S.]

11. After reviewing the literature of previously reported cases, Biermans records four cases of megacolon treated surgically. From his study of the subject he concludes that such patients should always be first examined carefully for sphincteric spasm and for abnormal valve-formation in the rectum. In megasigmoid he advises resection at two sessions. In congenital idiopathic megacolon he recommends colo-anastomosis, followed by resection. Volvulus or profuse diarrhea he considers imperative operative indications.

13. Mühsam reports 13 cases in which the Murphy button was used 14 times in making anastomoses of the large intestine, and from his experience concludes:

(*a*) That the Murphy button is suitable and justifiable for such use.

(*b*) That the risk of leakage is no greater than in suture anastomosis.

(*c*) That the principal danger is closure of the button by feces or foreign bodies.

(*d*) That early post-operative evacuation of the bowel is desirable.

(*e*) That at the slightest evidence of intestinal obstruction, the anastomosis should be inspected.

(*f*) That the advantages of employing the Murphy button are its relatively easy technic and shortening of the operation.

22. Ziegner presents a study of six cases, with excellent x-rays, from which he concludes that the coxitis of early childhood is usually an osteomyelitic metastasis, and generally appears in infancy. Coxitic dislocations he considers are principally spontaneous dislocations following rapid and extreme distention of the capsule, which after a time come to resemble congenital dislocations, and should be treated on the same principles. Even when there is extensive destruction of the upper epiphysis, he believes that the prognosis of the replaced hip is favorable. Prophylactically wide prompt incision is indicated in every suppurative coxitis of early childhood.

27. Stuckey collects from the literature 35 previously reported cases of retrograde intestinal incarceration, to which he adds 4 from his own observation; and from a study of this series reaches the following conclusions:

(1) The exact cause of retrograde incarceration is unknown.

(2) The rapidly progressive gangrene of the incarcerated coils depends on one of the following conditions: (*a*) The cutting off of the mesenteric vessels within the abdominal cavity by kinking. (*b*) The double strangulation of the mesentery in the hernial ring. (*c*) The cutting off of the vessels of the cecum and lower section of the ileum by kinking.

(3) The most reliable symptoms of retrograde incarceration are tenderness and local distention of the bowel directly overlying the hernia.

(4) Attempts at taxis in strangulated hernia should be absolutely rejected. The only rational treatment is immediate operation. [R. M. G.]

REVUE DE MÉDECINE.

SEPTEMBER, 1910.

1. PETRÉN. *Observation on the Treatment of Sciatica and Morbus Coxæ Senilis.*
2. CATOLA. *Investigations on the Central Nervous System of Children of Infirm Parents and Considerations of Pathological Predisposition.*
3. MARIE AND BEAUSSART. *Serum Diagnosis in Tuberculosis and the Etiology of Mental Diseases.*
4. *BERTIN AND GAYET. *Hereditary Syphilis and the Wassermann Reaction.*
5. *SALMON. *Pathological Sleep.*

4. Bertin and Gayet emphasize the importance of the serum reaction for syphilis in those cases of hereditary disease which lack the classical signs of the process. Hutchinson's triad is often absent, as well as the ordinary

tertiary lesions. The search for spirochetæ and the Wassermann reaction enable far more diagnoses than were made formerly.

5. In a most interesting article Salmon considers the conditions and causes of normal and pathological sleep. The physiological process is due to the stimulation by toxic products of metabolism of the sleep function in a stimulus which is normally neutralized by the glands of internal secretion, the hypophysis in particular. Normal sleep is not so profound that we cannot be roused at once and take on the proper functions of the body without pause.

But a morbid process exists, — "hypersomnie," — which is characterized by deep sleep at night, superseded by constant drowsiness during the day. Such individuals are difficult to rouse and tend at once to resume the deep sleep at any time, even during any of the voluntary activities of the body. Such a condition is found in the presence of excessive secretion of the hypophysis, diminished thyroid, ovarian and testicular secretion; as well as with tumors at the base of the brain or the vault of the pharynx, causing irritation of the hypophysis. The passive cerebral congestion found in persons subjected to rarefied air and that following epileptic seizures causes a toxic action, which results in an excessive and abnormal sleep.

This pathological sleep, unlike the physiological process, is the result of toxic substances which are present from overproduction, or from the failure of the internal glands to neutralize such poisons. These substances penetrate to the brain itself and cause chromatic hypersecretion.

2. Frugoni, C. *Clinical Studies on Alterations of the Respiratory Rhythm, with Special Reference to the Anginal and Neurotic Forms.*
3. *Giulio, P. *A Case of Acute Yellow Atrophy of the Liver Following Acute Alcoholic Intoxication.*

3. Giulio reports a case of acute yellow atrophy of the liver from Genoa. The total duration of the disease wa one week, and from the onset of grave symptoms (con vulsions, coma and collapse) three days. There was noth ing unusual in the case which is of interest only from the standpoint of etiology. Acute parenchymatous hepatitis can be produced by a number of pathogenic agencies which may be classified as follows:

(1) Infections — streptococcus, staphylococcus, B. coli and others.

(2) Auto-intoxications — from abnormal products of metabolism.

(3) Poisons — phosphorus, chloroform, alcohol.

This patient was an alcoholic and had just been through an acute intoxication. Chronic alcoholism is universally recognized as a predisposing cause of acute yellow atrophy because of its degenerating effect on the liver cells. Less well recognized is the influence of acute alcoholism as an exciting cause of this disease. [L. D. C.]

SURGICAL SECTION.

1. Gabaglio, R. *Fractures of the Carpal Scaphoid.* (To be continued.)
2. *Sabella, P. *Bilateral Ectopia and Sarcoma of the Testicle.*

2. Sabella reports an unusual case of bilateral complete retention of the testes, in which at the age of twenty-three there developed in each of the glands a tumor which, on removal by laparotomy, proved to be large round-cell sarcoma. At the end of a year after the operation there is no sign of recurrence or metastasis. In his discussion of the subject of ectopia testis, the author classes the varieties of retention as abdomino-lumbar (as in his case), iliac, inguinal and cruro-scrotal, the varieties of ectopia being sub-abdominal, crural and perineal. Pathogenetically he believes that malignant tumors of such retained or misplaced testes arise from the interstitial cells of the organ.

Miscellany.

ARMY MEDICAL CORPS EXAMINATION.

The Surgeon-General of the Army announces that the first of the preliminary examinations for the appointment of first lieutenants in the Army Medical Corps for the year 1911 will be held on Jan. 16, 1911, at points to be hereafter designated.

Full information concerning the examination can be procured upon application to the "Surgeon-General, U. S. Army, Washington, D. C." The essential requirements to securing an invitation are that the applicant shall be a citizen of the United States, shall be between twenty-two and thirty years of age, a graduate of a medical school legally authorized to confer the degree of doctor of medicine, shall be of good moral character and habits, and shall have had at least one year's hospital training or its equivalent in practice after graduation. The examinations will be held concurrently throughout the country at points where boards can be convened. Due consideration will be given to localities from which applications are received, in order to lessen the traveling expenses of applicants as much as possible.

The examination in subjects of general education (mathematics, geography, history, general literature and Latin) may be omitted in the case of applicants holding diplomas from reputable literary or scientific colleges, normal schools or high schools, or graduates of medical schools which require an entrance examination satisfactory to the faculty of the Army Medical School.

In order to perfect all necessary arrangements for the examination, applications must be complete and in possession of the Adjutant-General on or before Jan. 3, 1911. Early attention is, therefore, enjoined upon all intending applicants. There are at present seventy-six vacancies in the Medical Corps of the Army.

MEASLES AMONG THE ALEUTS.

The captain of the United States revenue cutter *Tahoma*, flagship of the Behring Sea patrol fleet, has recently reported at Port Townsend, Wash., that the native inhabitants of the Aleutian Islands are being rapidly exterminated by measles, tuberculosis and pneumonia. This affords another interesting illustration, like the history of the Kanakas in Hawaii, of the exalted, almost pestilential virulence assumed among primitive aborigines by infections of which civilized man has from long exposure acquired greater tolerance. Measles particularly, that "domestic cat among diseases," as Dr. Woods Hutchinson has called it, seems to recover among such peoples as the Aleuts pristine qualities that emphasize its relationship to the severer exanthemata. It has been recommended that the native population of the Aleutian Islands be assembled at suitable stations and placed under competent medical surveillance in the effort to check the ravages of these diseases until such time as a natural partial immunity to them may perhaps be developed.

APPOINTMENTS.

The following appointments have been made to the staff of the Rockefeller Institute for Medical Research: Francis Henry McCrudden, M.D., Chemist to the Hospital; Thomas S. Githens, M.D., Fellow in the Department of Physiology and Pharmacology; James B. Murphy, M.D., Fellow in the Department of Pathology and Bacteriology; A. R. Dochez, M.D., Bacteriologist to the Hospital; F. Medigreceanu, M.D., Laboratory Assistant to the Hospital; W. H. Manwaring, M.D., Assistant in Pathology.

SOCIETY NOTICES.

THE NEW ENGLAND HOSPITAL MEDICAL SOCIETY. — This society will meet at the Kensington Chambers, corner Boylston and Exeter streets, Room 203, on Thursday, Nov. 17, 1910, at 7.30 o'clock. Section of Surgery, Dr. Elizabeth T. Gray, chairman. Subject: Cæsarean Section. 1. "Short Résumé of the History of Cæsarean Section," Dr. E. T. Gray. 2. "Indications for Cæsarean Section, from the Obstetrician's Standpoint," Dr. Mary F. Hobart. 3. "Technique of the Operation," Dr. Mary A. Smith. 4. "The Immediate Results of Cæsarean Section," Dr. John T. Williams. 5. "The End Results of Cæsarean Section," Dr. Nathaniel R. Mason.

DR. BLANCHE A. DENIG,
Secretary.

NEW ENGLAND PEDIATRIC SOCIETY. — The twelfth meeting of the New England Pediatric Society will be held in Sprague Hall, Boston Medical Library, on Saturday, Nov. 26, at 8.15 P.M. 1. Business and nomination of officers. 2. "The Youthful Psychopath," J. W. Courtney, M.D., Boston. 3. "Proctoscopy and Sigmoidoscopy in Infancy as applied to Ileo-Colitis" (Preliminary report), Henry I. Bowditch, M.D., Boston. 4. "Examination of Spinal Fluids in Various Meningeal Conditions in Children," Wm. P. Lucas, M.D., Boston. 5. "Exhibition of a Fetal Monstrosity," James R. Torbert, M.D., Boston. 6. Election of officers. Light refreshments will be served after the meeting.

CHARLES P. PUTNAM, M.D., *President.* FRITZ B. TALBOT, M.D., *Secretary.*

ESSEX SOUTH DISTRICT MEDICAL SOCIETY. — The second meeting of the year will be held at the Belmont Hotel, Gloucester, Tuesday evening, Nov. 15. Dr. George C. Smith, of Boston, will speak on the "Treatment of Chronic Cardiac Affections." Dinner will be served promptly at 6.45 P.M.

GEORGE H. CRAY, M.D., *President.* WALTER G. PHIPPEN, M.D., *Secretary.*

AMERICAN ACADEMY OF MEDICINE. (Specializing in Medical Sociology.) — The fourth mid-year meeting will be held at the Lafayette Hotel, Buffalo, Thursday, Dec. 1, and Friday, Dec. 2, 1910, being a conference on "The Sociologic Influence of Hospitals and Dispensaries." Members of the profession and all others interested in the subject of the conference are invited to be present.

CHARLES McINTIRE, M.D., *Secretary,*
Easton, Pa.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. (A Memorial and Historical Society.) — A meeting of the society will be held in Sprague Hall, Boston Medical Library, on Monday evening, Nov. 14, 1910, at 8.15. Program: "The Doctrine of Vitalism in Medicine," Dr. M. G. Seelig, St. Louis. Memorial meeting to Dr. H. L. Burrell. Speakers: Dr. E. H. Bradford, Dr. F. S. Watson, Dr. G. H. Monks. The members of the Suffolk District Medical Society are cordially invited to be present.

J. G. MUMFORD, M.D., *President.* DANIEL FISKE JONES, M.D., *Secretary,*
195 Beacon Street.

SOUTH BOSTON MEDICAL SOCIETY. — This society will hold its regular meeting, Monday, Nov. 14, in Hobah Hall. The paper for the meeting will be read by Medical Examiner Magrath. Subject: "Medico-Legal Advice in Massachusetts for General Practitioner." Refreshments will be served.

FRED N. STUART, M.D., *President.* JOHN C. ROGERS, M.D., *Secretary.*

BOSTON MEDICAL LIBRARY IN CONJUNCTION WITH THE SUFFOLK DISTRICT MEDICAL SOCIETY. — Medical section meeting, John Ware Hall, Wednesday, Nov. 16, 1910, at 8.15 P.M. "Acute Poliomyelitis," John Lovett Morse, M.D. Discussion by Drs. R. W. Lovett, W. E. Paul and W. P. Lucas.

EDWIN A. LOCKE, M.D., *Secretary,*
311 Beacon Street.
HENRY JACKSON, M.D., *Chairman,*
380 Marlborough Street.

RECENT DEATHS.

DR. EDWARD HOLMAN HAMILL, who died on Oct. 30 at Chatham, N. J., was born in Alabama in 1843. He served throughout the Civil War as a captain in the Confederate Army. For some years past he had been consulting medical director of the Prudential Insurance Company of Newark, N. J.

DR. WILLIAM S. SEARLE, who died last week in Brooklyn, N. Y., was born in 1833. He was a graduate of the University of Pennsylvania and a founder and former vice-president of the New York State Board of Medical Examiners. He had practised medicine in Brooklyn since 1870. He is survived by three daughters and two sons.

DR. JOHN H. NESBITT, of New York, committed suicide by shooting, on Oct. 27, on board the White Star steamer *Arabic*, while on his way to England. He was suffering from nervous breakdown and had gone abroad in the hope of regaining his health. Dr. Nesbitt had been a police surgeon in New York for twenty-five years, and on account of his ill-health had been granted a two months' leave of absence from this service. He was born in New York City in 1854, and was graduated from the College of Physicians and Surgeons, New York, in 1875.

DR. CHARLES H. SHEPARD, of Brooklyn, N. Y., died on Oct. 29, in the eighty-sixth year of his age. He was graduated from the New York Medical College in 1859, and, notwithstanding his advanced age, was in active practice up to the time of his last illness.

DR. ROBERT HUNTER DUNCAN, of Brooklyn, N. Y., died on Oct. 31, at the Jamaica (Long Island) Hospital, from Bright's disease. He was born at Barrington, Nova Scotia, in 1862, and was a graduate of the Mount Ellison University at Sackville, New Brunswick, and of the College of Physicians and Surgeons of Baltimore. He later continued his medical studies in Edinburgh, Scotland, and for several years he was a ship's surgeon on the Pacific Mail line of steamers.

DR. CHARLES B. CURRAN, of Brooklyn, N. Y., died from pneumonia on Nov. 1. He was born in Brooklyn on Dec. 23, 1872, and was graduated from the Long Island College Hospital in 1893. For some time he served on the staff of St. Mary's Hospital, Brooklyn, and for fifteen years was an inspector in the Health Department.

DR. MICHAEL B. VAN BUSKIRK, of Aurora, Cayuga County, N. Y., died at the residence of his daughter in New York City on Oct. 30. He was graduated from the medical department of the University of New York in 1866.

DR. PAUL T. KIMBALL, a well-known physician of Lakewood, N. J., died suddenly from cardiac disease, on Nov. 2. He was a brother of Dr. Reuel B. Kimball, of New York, and forty-eight years of age. He was graduated from the College of Physicians and Surgeons, New York, in 1887, and afterwards served as interne at both the New York and the Woman's hospitals.

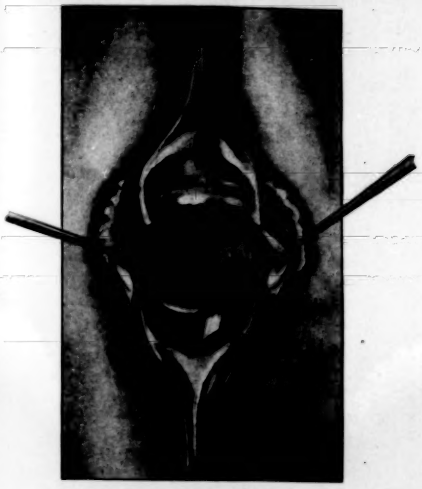

FIG. 1. Acquired atresia of the vagina showing pinhole opening where the septum had been incised for the relief of symptoms at the time of puberty.

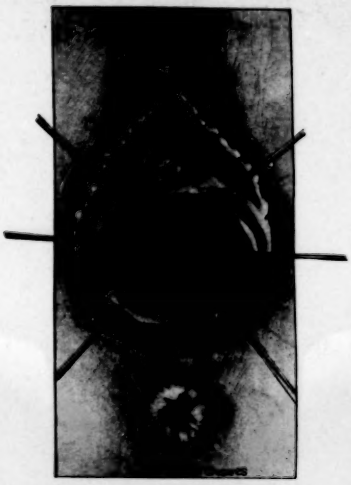

FIG. 2. Operation for acquired atresia of the vagina. The transverse septum has been dissected out, and the upper portion of the mucous membrane of the vagina united to the lower by interrupted catgut sutures.

FIG. 3. Operation for congenital absence of the vagina. The four flaps taken from the labia minora and the thighs are approximated over a glass form. The wounds where the flaps were removed are represented as sewed up with interrupted sutures. The pouch made by the four flaps is turned into the opening previously made by separating the bladder from the rectum.

FIG. 4. Operation for congenital absence of vagina. The glass form has been removed and the seams of the pouch completely sewed. The untied sutures seen issuing from the pouch were previously passed through the vault of the artificial opening made between the bladder and rectum. The pouch is inverted into the artificial opening and the stitches tied so as to prevent any prolapse of the pouch before it heals to the raw surface of the opening.

Original Articles.

OPERATIVE TREATMENT OF ATRESIA OF THE VAGINA.*

BY W. P. GRAVES, M.D., BOSTON.

ATRESIA of the vagina may be either acquired or congenital. The acquired form is by far the more common, being the result of an extensive adhesive vaginitis. Congenital atresia is due to defective embryological development and is always accompanied by other defects involving the genital organs.

ACQUIRED ATRESIA OF THE VAGINA.

The majority of cases of this condition represent the end result of a long-continued plastic vaginitis usually gonorrheal in origin and acquired before the age of puberty. The vaginal mucous membrane of the adult is peculiarly resistant to the gonococcus, and is rarely infected excepting secondarily, and then not frequently. The delicate undeveloped vaginal mucous membrane in the child, on the other hand, is extremely susceptible to a gonococcal infection, which causes a peculiarly profuse purulent vaginitis and one that persists with much obstinacy. Such a vaginitis on healing has a great tendency to plastic adhesions of the vaginal walls. The most common situation for these adhesions to take place is at the junction of the anterior and middle third of the vagina where the two walls are normally in constant contact. In this way the vagina becomes completely occluded, and when menstruation is established the catamenial flow is obstructed and retained in the vaginal pouch behind the adhesion. As this accumulation increases each month, pressure is exerted on the cicatricial adhesion, and it is gradually stretched out into a well-marked membrane or diaphragm, which under sufficient pressure from behind may protrude from the vaginal orifice. Sometimes the anterior and posterior walls of the vagina may be completely glued together throughout the whole length of the vagina, a condition which is illustrated by Case 4 of this article. The plastic adhesion may take place at the orifice and cause atresia of the hymen, or the labia may be glued together and the vulva completely obliterated. Such conditions are due to the fact that, in all cases of purulent vaginitis in children, the vulva is involved, and is probably often the primary locus of infection, the epithelium of the vulva, like that of the vagina, being extremely susceptible to infection in children while very resistant in the adult. The present paper is confined to only those cases where the adhesion takes place in the vagina.

Acquired atresia of the vagina may also occur in adult women and may be the result of adhesions forming after a vaginitis following severe lacerations at childbirth. Adhesions from this cause usually occur much higher up in the vagina, and sometimes may include only the cervix, in which case atresia of the cervical canal results. Senile vaginitis is not an uncommon cause of atresia of the vagina, but does not usually give rise to serious trouble because of the absence of menstruation. It sometimes happens, however, that secretions may collect behind an atresia even in women who have passed the menopause, and such a condition is illustrated by Case 3.

When the atresia has been acquired in early childhood, symptoms do not ordinarily manifest themselves until the age of puberty, though Kelly reports the case of a child where a large amount of mucus accumulated behind the atresia, causing a considerable tumor and indicating the necessity for an operation. At puberty the menstrual blood accumulates in the vagina behind the adhesive membrane, distends it and makes a tumor. If the condition is not relieved, the accumulation of blood added to by each menstrual period gradually distends first the vagina and then the uterus, and a very large tumor occupying a considerable portion of the abdominal cavity may be formed. In severe cases, as in Case 4, a double hematosalpinx may form. The pain is at first periodic, but may become continuous as the tumor enlarges.

The operation for atresia is one that is attended with considerable danger of fatal sepsis, and every precaution should be taken to prevent infection. After evacuating the old menstrual blood, which is always of a thick tarry consistency, the cavities of the vagina and uterus should be most carefully irrigated. Where there is a definite membrane occluding the vagina, the method of operation is of extreme importance. Cases 1 and 2 illustrate well the results which may ensue after an operation which consists only of an incision in the occluding membrane and the evacuation of the contents. The opening made by such an incision sometimes closes up entirely, but more often results in one or more pinhole apertures through which the menstrual blood may partially flow. A certain amount of mucus and blood is dammed back into the vagina, becomes foully infected and produces the dire results seen in Cases 1 and 2. In order to leave the vagina in a permanently normal condition the occluding membrane should be completely dissected out and the wound edges approximated with great care. Such a wound will heal up by first intention even in the face of a badly septic discharge. The details of the operation for dissecting out an occluding membrane are as follows:

OPERATION FOR ACQUIRED ATRESIA OF THE VAGINA.

After the septum has been incised and the contents of the space beyond have been removed, there should be a thorough cleansing of the parts. The edges of the septum should then be trimmed flush with the walls of the vagina. All scar tissue should be removed so as to prevent a future contraction. When the septum has been completely cleared away it will be found that there remains a denuded area which extends like a ring around the inner circumference of the vagina. The

* The drawings illustrating this article have been previously published in the *American Practice of Surgery*, vol. vi.

mucous membrane of the upper portion of the vagina should then be drawn down and approximated to that of the lower portion by interrupted catgut sutures. Such an operation should restore perfectly the normal caliber of the vagina and should not be followed by a tendency to the development of a stricture. The use of antiseptic douches twice or three times daily should be begun the day after the operation and should be kept up until the discharge completely disappears.

The following are four cases of acquired atresia which have occurred in my experience.

CASE 1. Mrs. A., age forty-five. Referred by Dr. Charles N. Cutler. Patient gave a history of a long-continued severe vaginitis at the age of ten, following an injury to the external genitals from falling astride a fence. At the time of puberty she had the usual symptoms of atresia, namely, great pain at the time for a monthly period, but without appearance of blood. She was operated upon, the operation apparently consisting of a puncture of the occluding membrane with an evacuation of the secretions. The patient was married at about the age of twenty-four. She menstruated regularly from the time of the operation, the menstrual flow being sometimes foul. When I saw the patient she was suffering from an extremely severe pruritus vulvæ. Examination showed a white leathery appearance of the external genitals which represented an early stage of the condition called kraurosis. Vaginal examination showed a well-developed membrane across the vagina situated at the junction of the outer and middle third. Through the membrane was a pinhole opening which doubtless represented the puncture which had been performed early in life. The patient had menstruated incompletely through this opening, and as the secretions, which were continuously partially dammed back by the occluding membrane, had become infected, a chronic pruritus had been caused by the irritating discharges. An operation was performed on the patient according to the method described above for acquired atresia, the contour of the vagina being entirely restored to its normal character. The condition of kraurosis, though relieved for a time, continued, however, to develop and necessitated a complete removal of the vulva, by which the patient was entirely cured.

CASE 2. Miss L., age twenty-two. Referred by Dr. Charles N. Cutler. Patient had a history of early vaginitis, monthly pain without blood at the age of puberty, and an operation of puncture of the vaginal membrane with evacuation of contents of the vagina. The patient menstruated incompletely and had frequent discharges of such a foul nature that she was extremely offensive to people about her. Examination showed a condition exactly like that of Case 1, namely, a membrane at the junction of the middle and outer third of the vagina, with a pinhole opening through which exuded a purulent discharge of a nauseating odor. An operation was performed by the method described above, a large amount of bloody purulent material being evacuated from the upper portion of the vagina, which had been distended. The vaginal mucous membrane showed a condition of the most severe inflammation. The wound of the operation healed by first intention and the patient after a period of local treatment for the inflamed vaginal mucous membrane made a complete recovery.

CASE 3. Mrs. M., age fifty-one. Referred by Dr. Charles N. Cutler. This patient had had several attacks of severe pelvic pain which were relieved after the sudden discharge of a large amount of mucopurulent matter. Examination of the patient showed that she had had a plastic vaginitis of the upper part of the vagina so that the cervix was entirely occluded. Pelvic examination showed that the patient also had evidences of an old pelvic inflammatory disease. The cervical canal was opened without ether, and after an unsuccessful attempt to keep the canal patent, I decided to perform an hysterectomy. The pelvis was found full of old adhesions. The pelvic organs were removed and the patient made a good recovery.

CASE 4. Miss E., age fourteen. Previous to my seeing her this patient had had two operations for supposed congenital atresia of the vagina. She had the typical symptoms of atresia accompanying functionating pelvic organs. Examination showed occlusion of the vagina less than an inch from the introitus. Rectal examination showed a very large tender uterus with tubal masses on both sides of the pelvis. There were signs of a mild pelvic peritonitis, and the patient was running some temperature. At the operation the anterior and posterior walls of the vagina were found completely glued together and the surfaces were separated with considerable difficulty. When the vault of the vagina was reached, no signs of a cervix or of a cervical canal could be seen. The cervical canal was found after much trouble and the uterus was evacuated of a large amount of dark, semi-fluid material. The uterine cavity was thoroughly irrigated. An incision was then made in the median line of the abdomen and both tubes were found to be enormously distended with blood. There was some pelvic peritonitis. The tubes were removed and the pelvis was drained. This operation did not prove satisfactory as it was found impossible to keep the cervical canal patent. A glass-stem pessary was kept in the uterus several times for long periods. The pessary, however, kept up an inflammatory condition and the cervical canal each time closed up within a few days after its removal. The patient's condition finally became a serious one, and it was necessary to perform an hysterectomy, which was followed by a complete recovery. Although this case had been pronounced one of congenital atresia by several surgeons who had seen her, I have classified it as of the acquired type, as all the pelvic organs were perfectly normal. Although no history could be gained, this girl unquestionably had had a vaginitis in childhood which had caused a complete atresia of the whole length of the vagina.

CONGENITAL ATRESIA.

Many cases of congenital atresia do not require operation because they are frequently associated with defective development, or partial absence of the internal pelvic organs, so that menstruation has not been established. It sometimes happens, however, that secondary sexual characters are normally developed, and operation for the purpose of coition is demanded by the patient. In other cases the internal pelvic organs may functionate normally, and it is important to establish an artificial vagina for the purpose of drainage. The establishment of a permanent artificial vagina is a matter of extreme difficulty, and only a few successful cases have been reported. The operation described in this article is based on successful operations by Burrage and Abbey, in which flaps were turned in from neighboring areas. One writer has been successful in grafting in the vaginal tissue removed from a case of cystocele. The following is the technic of the operation which I

have devised for congenital atresia based on the operations of Burrage and Abbey, and which in the only case where I have had an opportunity to try it was successful.

The patient is placed in the perineal position. A superficial transverse incision is made just below the urethra. Through this transverse slit the bladder and rectum are slowly dissected apart with the finger. The forefinger of the left hand should be kept in the rectum, and some blunt instrument like a urethral dilator should be held in the bladder by an assistant. The dissection should be carried by the right forefinger, the left forefinger behind and the blunt instrument in front acting as guides to prevent tearing into the wall of the rectum or bladder. In this way an artificial opening can be made of the exact proportions of the normal vagina. Care should be exercised not to enter the abdominal cavity. The next step is to line this cavity with a pouch of skin made up of flaps turned in from the surrounding parts. To accomplish this, the two labia minora are dissected off, from above downward, in such a manner as to leave a pedicle sufficiently large to furnish good circulation. The two surfaces are then split apart so that two paddle-shaped flaps remain. There should then be dissected from the inner side of the thigh two similar flaps which have their bases at the two lower corners of the artificial opening. All four flaps are then sewed together over a glass form, as shown in the cut (Fig. 4). Before the flaps are sewed together several catgut sutures, with the ends left long, should be placed in the vault of the artificial cavity. When the skin pouch has been nearly completed, the glass form is removed and the catgut sutures are brought out through the skin pouch. The pouch is then inverted and the sutures are tied in such a manner that the pouch fits snugly into the artificial cavity.

The history of the case in which the preceding operation was successfully performed follows:

Miss M., age twenty-seven, was a young woman of apparently normal development and attractive appearance. She gave a history of never having menstruated. She had had normal sexual feelings and was engaged to be married. Examination showed normal development of breasts, hips and external genitals. Further examination revealed complete absence of the vagina, there not even being a dimple to indicate the introitus. By rectal examination no sign of uterus or ovaries could be felt.

The operation described above was performed, and the pouch formed by the turned-in flaps from the labia minora and from the thigh healed by first intention with the exception of a small area in the vault, and a permanent functionating vagina was established.

CANCER OF THE SCROTUM.

BY ROBERT M. GREEN, M.D., BOSTON.

CANCER of the scrotum, or chimneysweep's disease, was apparently first described as a pathologic entity in 1775 by Percivall Pott. In a pamphlet, or Chirurgical Observation, entitled "Cancer Scroti," he writes of it as follows:

"There is a disease peculiar to a certain set of people, which has not, at least to my knowledge, been publickly noticed; I mean the chimney-sweeper's cancer.

"It is a disease which always makes its first attack on, and its first appearance in, the inferior part of the scrotum, where it produces a superficial, painful, ragged, ill-looking sore, with hard and rising edges; the trade call it the soot-wart. I never saw it under the age of puberty, which is, I suppose, one reason why it is generally taken, both by patient and surgeon, for venereal, and, being treated with mercurials, is thereby soon and much exasperated; in no great length of time, it pervades the skin, dartos and membranes of the scrotum, and seizes the testicle, which it enlarges, hardens and renders truly and thoroughly distempered; from whence it makes its way up the spermatic process into the abdomen, most frequently indurating and spoiling the inguinal glands. When arrived within the abdomen, it affects some of the viscera, and then very soon becomes painfully destructive.

"The fate of these people seems singularly hard; in their early infancy they are most frequently treated with great brutality, and almost starved with cold and hunger; they are thrust up narrow and sometimes hot chimnies, where they are bruised, burned and almost suffocated; and when they get to puberty, become peculiarly liable to a most noisome, painful and fatal disease.

"Of this last circumstance there is not the least doubt, though perhaps it may not have been sufficiently attended to, to make it generally known. Other people have cancers of the same parts; and so have others beside lead-workers the Poictou colic and the consequent paralysis; but it is nevertheless a disease to which they are peculiarly liable; and so are chimneysweepers to the cancer of the scrotum and testicles.

"If there be any chance of putting a stop to or preventing this mischief, it must be by the immediate removal of the part affected, — I mean that part of the scrotum where the sore is, — for if it be suffered to remain until the virus has seized the testicle, it is generally too late even for castration. I have many times made the experiment, but though the sores, after such operation, have, in some instances, healed kindly, and the patients have gone from the hospital seemingly well, yet in the space of a few months it has generally happened that they have returned either with the same disease in the other testicle, or in the glands of the groin, or with such wan complexions, such pale, leaden countenances, such a total loss of strength, and such frequent and acute internal pains, as have sufficiently proved a diseased state of some of the viscera, and which have soon been followed by a painful death.

"If extirpation ever bids fair for the cure of a cancer, it seems to be in this case; but then the operation should be immediate, and before the habit is tainted. The disease, in these people, seems to derive its origin from a lodgement of soot in the rugæ of the scrotum, and at first not to be a disease of the habit. In other cases of a

cancerous nature, in which the habit is too frequently concerned, we have not often so fair a prospect of success by the removal of the distempered part, and are obliged to be content with means which I wish I could say were truly palliative; but here the subjects are young; in general in good health, at least at first; the disease brought on them by their occupation, and in all probability local, which last circumstance may, I think, be fairly presumed from its always seizing the same part: all this makes it (at first) a very different case from a cancer which appears in an elderly man, whose fluids are become acrimonious from time as well as other causes; or from the same kind of complaint in women who have ceased to menstruate. But be all this as it may, the scrotum is no vital organ, nor can the loss of a part of it ever be attended with any, the smallest degree of inconvenience; and if a life can be preserved by the removal of all that portion that is distempered, it will be a very good and easy composition, for when the disease has got head, it is rapid in its progress, painful in all its attacks and most certainly destructive in its event."

This passage has become a classic description of the disease, as vivid as it is accurate. Even before Pott's time, cases, evidently cancer of the scrotum, had been reported, by Bassius in 1731, and by Treyling in 1740. But it remained for the great English surgeon to name the condition and discuss its character as an occupation-disease, which has so closely connected it with his own city, London, the home of chimneysweeps.

Following Pott's article, the disease was generally recognized, and cases of it began to be reported from time to time. Everywhere it was regarded as an English disease, and its etiologic connection with chimneysweeping was unquestioned. Thus in 1835, James Syme, of Edinburgh, writes:

"Though this disease would seem to be not uncommon in London and other large towns, it is never met with in Edinburgh, except in persons who have begun to suffer from it elsewhere; and it is accordingly so rare here that during the whole period of my connection with the Infirmary, as student and surgeon, I have not seen an instance of it either there or in private. This immunity of the trade in Edinburgh from a complaint which constitutes a serious scourge to it in other places, seems at first sight easily accounted for by the mode of sweeping chimneys here, which is effected not by climbing boys, except in the case of some very few particularly constructed vents, but by letting down from the top a broom, to which a weight is attached, and which, being then alternately drawn up and allowed to descend, completely attains the object in view. But boys seldom climb after the age of puberty, as they then become too large for the purpose; while, according to Mr. Pott and other practical writers, the disease is hardly ever observed at an earlier period of life, and usually occurs at a much later one. The theory of the men themselves is, that the body, from being saturated or poisoned, as they express it, by the large quantities of soot they are forced to swallow in their youth, acquires a predisposition to the disease, which, however, seldom actually appears until about the middle period of life." In the case which he reports, however, the patient, "from being of small stature, and extremely thin wiry make, has never abandoned the practice of climbing, boasting that an aperture twelve inches by nine inches is quite sufficient for his passage. He became an apprentice at five years of age in London, and remained there sixteen years, afterwards having no settled residence, but traveling about from place to place."

The attribution of the disease to the swallowing of soot was, of course, a popular fallacy, in which Syme doubtless did not share. A more reasonable theory of its causation had indeed already been stated in 1808 by Sir James Earle, in his second edition of "The Chirurgical Works of Percivall Pott." In a footnote to the article on cancer of the scrotum, he says:

"From the soot being collected and remaining in the moist rugæ of the scrotum, it is not difficult to conceive why the disease should generally begin in that part; but I have seen the true soot-wart in the face of a chimneysweeper, just under the left eye, who had never suffered from the disease in any other part, though he said he had sometimes felt little hardnesses in the scrotum, which, when they grew troublesome, he picked off; but he had never perceived any sore, ulceration or considerable hardness in that part." And in a later note, he continues: "This species of cancer, which Mr. Pott has so accurately described, appears to be produced by some peculiar acrimonious quality in soot, when incorporated and fermenting on the skin of some persons whose constitutions are disposed to undergo a certain change, or receive a new modification of their inherent properties. As chimneysweepers are in the constant habit of being in contact with soot, it follows that they must be most liable to a disease which is evidently caused by it; but, as was before observed, those only whose constitutions are disposed to receive the poison are infected, not one in many hundreds being injured by it. Mr. Pott seemed to suppose that this species of cancer was peculiar to chimneysweepers, but I have strong grounds for thinking that he was mistaken in that idea. There are instances, though I believe them to be very rare (as I know no one, either author or practitioner, who has noticed them), yet there are instances of other persons being infected by the contact or effluvia of soot; and as a caution for every one to be careful of handling it, or in any way being exposed to its action, I will relate the case of a man who was attacked with this dreadful disease to a most lamentable degree and was brought into the hospital. The scrotum and testes, with the spermatic cords, together with the glands in the groin, were included in a large phagedenic ulcer. The nature of the disease was so marked and evident that I took for granted that he was a chimneysweeper, and was much surprised to find that his business was quite of another kind. I could not, however, avoid repeatedly asking him if he had ever had any thing to do with sweeping chimneys; he

Cancer of the scrotum. (From specimen in the Warren Museum, Harvard Medical School.)

assured me not. Some time after he told me that, on considering the questions which I had so often urged, he recollected that not many years before he had lodged at the house of a chimneysweeper, in the apartments of which soot-bags and soot were deposited. He did not appear very accurate in his account, but thought on recollection that the complaint began in the scrotum soon after he left the chimneysweeper's house. This goes merely to prove that soot in substance, or perhaps the volatile parts of it, have the power of producing the disease; and not anything peculiar to the occupation or manner of life to which chimneysweepers are subject. Probably the man's body, or his linen, were liable to be daubed with soot, or the dust arising from it; and the scrotum was first affected, as it is among chimneysweepers, for the reason before given: that of the moist rugæ retaining the poison more readily than other parts."

Sir James Earle's son Henry, assistant surgeon to St. Bartholomew's, and surgeon to the Foundling Hospital, writes (Med-Chir. Trans., xii, 297):

"The disease . . . is invariably produced by the irritation of the soot applied to the rugæ of the skin. The characters of the complaint are peculiar, commencing in a warty excrescence which in some cases will remain nearly stationary for several months, or even years. After a time the excrescence discharges a thin acrimonious ichor, which excoriates the surrounding skin. Ulceration now takes place in the center, and the edges of the wound become everted and throw out a luxuriant growth, with schirrous hardness, which discharges a very fetid irritating matter. The most common situation for this complaint is the lower part of the scrotum; but this rule is not without exceptions. . . . As the disease advances, the parts immediately contiguous become affected; it spreads downwards to the perineum, and if not arrested will include the whole scrotum; at the same time it not infrequently extends itself to one or both testicles. When the testicle is first affected, it becomes firmly connected with the diseased scrotum; it enlarges and becomes greatly indurated; ulceration and sometimes sloughing then take place, leaving a deep excavated ulcer that penetrates into the body of the testis, which does not appear disposed to the formation of fungous growth, similar to what occurs when the scrotum is the seat of the disease. The same observation applies when the complaint has extended itself to the inguinal glands; its progress in glandular structures appears to be more rapidly destructive without the slightest effort at reparation. The disease, in every instance that I have seen, except one, extended itself to the parts immediately contiguous. The inguinal glands are often enlarged, but they will generally subside on the removal of the diseased scrotum, clearly proving that the disease is not commonly communicated in the course of the absorbents. This is a very important feature in the complaint and one which most materially influences the prognosis and treatment. . . . Even where the testicle is affected, the disease is confined, for a time, to that gland, but it subsequently extends itself up the spermatic cord into the cavity of the abdomen, where it proves rapidly destructive. Not only is the discharge from the sore very fetid, but the perspiration from the whole body, which is generally copious, has a very peculiar ammoniacal odor, which cannot be mistaken when once recognized. . . .

". . . The rare occurrence of this complaint may be referred to another cause, namely, there are strong reasons for presuming that a constitutional predisposition is required, which renders the individual susceptible to the action of the soot. If this was not the case, and if there was anything of a very acrimonious nature in soot, would it not more frequently affect the children, whose skins are far more delicate, and who are much more exposed to its constant application? Among those who have been affected, and who have fallen under my observation, several had been employed in the trade for above twenty years before they became affected, and it is more reasonable to conclude that some alteration had taken place in their constitutions which rendered them susceptible of the irritation than that it was the immediate result of any peculiar quality in the soot. This opinion is much confirmed by instances in which different branches of the same family have been subject to the disease at a particular period of their lives. In some instances, two or three generations have fallen victims to the ravages of this disease, for the business is so lucrative that they are unwilling to abandon it. . . .

". . . As far as my observation goes, no topical applications or internal remedies have the slightest influence over the disease. The scalpel is the only resource, and that may be resorted to with the most confident expectation of success provided the whole of the diseased mass can be removed. Even where the inguinal glands are enlarged, this ought to be attempted. . . . Where the testicle is affected, provided the spermatic cord has not participated, it will be right to give the patient the chance of recovery rather than abandon him to a miserable and painful death. . . .

". . . It may appear rather an anomaly to affirm that a certain state of constitution is required for the production of this disease, and at the same time to advocate its locality, yet such are the conclusions which numerous facts appear to warrant, and I feel quite confident of being able to eradicate the complaint by a complete removal of the diseased portion, and the subsequent abandonment of the occupation of a sweep. As the disease is sometimes rapid in its progress, no time should be lost in making useless trials of remedies, but the operation should be at once and extensively performed."

In 1832, Travers writes (in Med.-Chir. Trans., xvii, 344):

"I may here shortly notice the cancer scroti, or chimneysweepers' cancer, which is a peculiar form of malignant ulceration, more truly local than any in its origin. But although it is impossible

to disconnect the origin of this sore and the occupation of the patient, how seldom have we seen the boys so much employed in this trade the subjects of it; their wounds and excoriations show no tendency averse to healing. The soot irritates in the adult to the formation of a hard pimple, which passes slowly through the stages of suppuration and scabbing to ulceration. The edge is hard and gibbous and everted, the surface of an ochre-red hue. The disease resembles the lupus of the cheek and eyelids in destroying the skin and cellular texture, leaving the testicles and ligamentous covering of the crura penis, as that does the sclerotic, bare and wasted, but otherwise uninjured. This sore has no tendency to slough or penetrate deeply by ulceration. The lymphatic glands are rarely and seldom specifically affected. The disease returns after extensive removal. . . . The patient dies hertic, tabid and commonly exhibits pulmonary tubercles, or the small white tubercle of scrofula on the serous membrane, either of the chest or abdomen. I am very doubtful of its identity with scirrhous cancer. The natural secretion, confined by the soot, which obstructs the sebaceous follicles and exhalant orifices, becomes an irritant and gives occasion to the inflammation, but the age and perhaps the habits predispose to the malignant character, which renders it incurable and ultimately fatal. The disease is of very variable activity, sometimes occupying years in its progress."

Sir Astley Cooper, in his "Observations on the Structure and Diseases of the Testis," London, 1830, says of the chimneysweeper's cancer:

"This disease has always appeared to me to be one of the most curious to which the human body is liable. The person who is brought up as a chimneysweeper, besides being exposed in his childhood to the horrors and apprehension of climbing to dangerous and giddy heights, in his boyhood suffering great cruelty and severe deprivations, and in his manhood being almost an alien from society, is liable to a disease which is altogether the produce of the loathsome pursuit in which he is engaged.

"The soot, to the application of which he is constantly exposed, harboring in the wrinkles of the skin, where the cuticle is thin and the cutis is highly vascular, produces in many of these persons an irritation, followed by an ulceration, which bears so strong a resemblance to cancer as to have received that appellation, and it certainly strongly resembles cancer of the lip in several of its circumstances.

"This disease I have only seen in two parts of the body, viz., upon the scrotum and upon the cheek. On the former it is very frequent; in the latter I have only seen it in two instances. In the first, the sore was seated in the center of the cheek, in a very old man, whose face was wrinkled from age, and, therefore, liable to retain a quantity of soot, which irritated and wrinkled in the skin until it produced the symptoms I shall directly describe. In the second case, the disease began on the cheek, near the angle of the mouth, and it extended both to the upper and under lip. . . .

"The first appearance of the disease is in a wart upon the scrotum, which appears broken upon its surface. Upon this wart an incrustation forms, and continues to cover the surface. If this incrustation be rubbed away, or picked off, the papillæ on the surface of the wart appear excoriated, red and broken and issue a slight discharge upon the surface. An incrustation again appears upon the wart, which remains until accident or the progress of ulceration remove it, and then the surface appears highly vascular and discharges a bloody serum. Still the surface becomes encrusted, until at length an ulcer of some extent forms under it. When the sore is carefully examined, it will be found hard, its edges indurated and everted, and its surface unequally vascular, so that it is yellow in some parts, red and vascular in others. It discharges a bloody serum, the smell of which is often very offensive, but still a purulent discharge is sometimes observed.

"At first the person complains more of a troublesome itching than of pain, but as the disease advances, darting pinching pain, with heat, shoots through the part, as in most other diseases of specific nature. As the ulcer proceeds, it even reaches the tunica vaginalis, hardens it and affects the surface of the testis. After the disease has extensively ulcerated, the absorbent glands in the groin become affected, one or more being hard and swollen; it inflames, is poulticed and fomented, and it breaks, discharging a bloody serum with some pus. These glands proceed slowly, ulcerating with a hardened surface and with everted edges, discharging serum from some parts of the surface, and a curd-like matter, or white sloughs, from others. At length a deep chasm is formed in the groin by ulceration; in others, an extensive sore; in the former case, the femoral vessels, or a large branch of them, are exposed and ulcerated, so as to destroy by free and sudden hemorrhage; in the latter, the patient is slowly exhausted by irritation, restlessness and discharge. The scrotum is in some cases nearly destroyed by ulceration.

"Upon dissection of the parts removed in the operation . . . it will be found . . . that the surface of the cellular membrane surrounding the ulcer is filled with a white scirrhous substance very little vascular, affording very much the same appearance as a similar incision into a cancer of the lip. When the glands in the groin are examined, they are found to be altered from their natural appearance and are enlarged and hardened, containing a white solid in some parts, a soft, white, curd-like matter in others; high vascularity in some parts and entire absence of it in others. I have known this disease occur at various ages from twenty-six to eighty years.

"From the number of persons who pursue this occupation, and the comparatively few affected by the application of soot, it would appear that there is something, either in the constitution or the parts of some individuals, which disposes to its production. I am inclined to believe that it depends more upon local circumstances than upon

the constitution. . . . I believe that it is a thin cuticle and an irritable skin, which permit the soot to produce its peculiar irritation and effusion; and that it spreads both by simple extension of surface and by the irritation of the absorbent glands.

"Medicine has no power over this disease, at least not any that I have tried; and all local applications, used with a view directly to heal the part, are of no avail.

"It admits only of two modes of procedure — the one to destroy it by sloughing; the other to remove it by excision.

"A dram of the oxide of arsenic, well mixed with one ounce of the ceratum cetacii, is to be thickly spread upon lint and applied upon the sore, upon which it is to remain for twelve hours, and is to be succeeded by a poultice. A slough is produced by the arsenic, which separates in a few days and a healthy surface succeeds; but if at any part the old and malignant leaven appear, the arsenic must be again applied until an entirely new surface be produced. If the glands be enlarged or hardened, the above application will increase them, and it ought not to be used. If the disease be removed by the knife, the operation is a simple piece of dissection. Enlarged glands in the groin are not to positively forbid the operation as they are sometimes increased from simple irritation only; and as the removal of a portion of the scrotum is little painful, soon performed and unattended with danger, the patient should have this chance of recovery given him.

". . . After the removal of the diseased portion of the scrotum, the vessels are, although small, apt to bleed profusely and to be with difficulty stopped by pressure; it is, therefore, desirable to secure every small vessel which bleeds freely, and not to apply any dressing upon the part, or to suffer the patient to get into bed; but he should be kept cool, and in the recumbent posture, as the scrotum will be then contracted. When the bleeding has ceased, the edges of the wound may be brought together by sutures."

The use of arsenic in the treatment of epithelioma is well-known, for it is a principal ingredient of the common "cancer-pastes." Singularly enough, arsenic has been also supposed to produce a condition analogous to chimneysweeps' disease. In an interesting work entitled "Pharmacologia," published in New York in 1822, Paris writes as follows (p. 208) of the local irritant effects of arsenic:

"The poisonous effects of arsenious acid are so amply detailed in medical works that it would be superfluous to dwell upon them; it may, however, be interesting and useful to record an account of the pernicious influence of arsenical fumes upon organized beings, as I have been enabled to ascertain in the copper-smelting works of Cornwall and Wales; this influence is very apparent in the condition both of the animals and vegetables in the vicinity; horses and cows commonly lose their hoofs, and the latter are often to be seen in the neighboring pastures crawling on their knees and not infrequently suffering from a cancerous affection in their rumps. . . . It deserves notice that the smelters are occasionally affected with a cancerous disease in the scrotum similar to that which infests chimneysweepers, and it is singular that Stahl, in describing the putrescent tendency in the bodies of those who die from this poison, mentions in particular the gangrenous appearance of these parts. . . . As an external application, arsenic has long been extolled in the cure of cancers."

Bell, in an article on "Paraffin Epithelioma of the Scrotum," in *Edinburgh Medical Journal*, xxii, 135, says:

"The name, 'chimneysweep's cancer,' is an admissible one, from old associations and long usage. 'Scrotal soot cancer,' though it implies a theory, has never been so much adopted. By these names, surgeons describe a disease of the nature of epithelioma, attacking first, as a local disease, the scrotum, yet, if left, apt, by infecting the glands, to poison the system, though, at its outset, it is merely a result of a local specific irritation. *Local*, because its seat of election seems to depend simply on the difficulty of cleansing the soot stains from the rugæ of the pendulous and mobile scrotum. *Specific*, because it seems to result from the contact only of certain varieties of soot — coal, not wood, even of coal soot, from English rather than Scotch coal.

"Chimneysweep's cancer is now a disease of comparative rarity. This is explained by the legislation against climbing boys, and invariable use of brushes and other mechanical appliances.

"But, if chimneysweep's cancer is rare, and becoming rarer every year, I believe we are to find a successor for it in a malady affecting the laborers exposed to the fumes of paraffin in shale works. Of this disease, — epithelioma of the scrotum, ascribed by patients to paraffin fumes and contact with the oil, — I have seen two cases within the last eighteen months."

(To be continued.)

CLINICAL AND BACTERIOLOGICAL RESEARCHES ON MIKULICZ'S METHOD OF RENDERING THE PERITONEUM RESISTANT TO SURGICAL INFECTIONS.

BY PROF. E. DE PAOLI, M.D.,

Director of the Surgical Clinic of the University of Perugia, Italy.

THE author believes that Mikulicz's method should be practised by surgeons who are about to perform celiotomy for lesions in which there has been an external cause as well as those in which the disease has originated within the peritoneal cavity, in both of which there is danger of infection of the peritoneum following abdominal section.

The author has practised this method in all cases in which celiotomy has been performed, and since the time when he first began to use it his results, which previously had not been perfectly satisfactory, have been much better. Septic

peritonitis has practically disappeared from his wards in spite of the fact that there is no isolation of septic cases, and also that his patients usually delay a long time before deciding to submit to an operation. The author has at present a series of 155 cases of celiotomy, in which a preventive injection had been given before operation, with but a single death from septic peritonitis. Such a series is quite exceptional in his experience, which has now extended over a period of many years. The immunizing injection of nucleinate of sodium offers, in addition, this advantage, in that it serves to measure with precision the natural powers of resistance of the patient who is about to be operated upon. If after the injection there is a satisfactory hyperleucocytosis this is the proof that the powers of resistance are sufficient; if, on the contrary, hyperleucocytosis does not follow injection of the drug, we know that the means of defense against infection are decidedly lowered. In the first case we may operate with confidence; in the second, we should abstain from operating, if possible, until the patient is in a better condition. In the first trials of the drug by Miyath and Renner disagreeable sequelæ followed the administration, such as local pain, often very severe, nausea and vomiting, general depression, chills, more or less fever, and sometimes toxic symptoms which gave rise to considerable anxiety. These effects were always transitory and invariably passed away at the end of a few hours, but they frightened surgeon and patient alike on the eve of a serious operation. It is probable that these disagreeable sequelæ have prevented the vulgarization of Mikulicz's method. These unfavorable symptoms can be rendered much less severe by substituting for the nucleinate of sodium employed by Mikulicz a preparation from which all the free albumen has been removed, that is to say, by using a salt of nucleinic acid which is neutral, anhydrous and perfectly pure. It is also preferable to give the injection thirty-six to forty-eight hours before the operation instead of ten hours before; in this way the disagreeable effects will have passed by and will not have an unfavorable influence on the intervention. One should not give the large doses advised by Renner when about to operate for appendicitis in either the acute or the chronic forms, cholecystitis, simple or calculous, and tuberculosis; in these diseases the general reaction after the injection is often intense, and there is also frequently in these conditions a spontaneous hyperleucocytosis.

Bacteriologic studies of the blood of patients before and after the injection of nucleinate of sodium have shown an increase in the bactericidal power of the blood serum with reference to the culture of the bacterium coli. This result is very remarkable because it serves to show how the drug must act in protecting the peritoneum against the germ very commonly found in septic peritonitis. This increase in the bactericidal power of the serum after the injection has not been observed with the staphylococcus pyogenes. Perhaps bacteriotropic substances are formed which are somewhat different from bactericidal substances. Future investigations must clear up this obscurity.

The blood of patients who have received the injection shows constantly a diminution in its viscidity which depends upon the fewer red blood globules and hemoglobine; the injection, therefore, immediately causes hemolysis. This must be borne in mind.

An ideal kemotatic substance should produce a good hyperleucocytosis and should tend to immunize the peritoneum against infection without detriment to the patient. Nucleinate of sodium freed of its albumen approaches this ideal without quite reaching it. We should, therefore, employ Mikulicz's method when there is danger of operatory infection, at the same time bearing in mind that it does not give absolute immunization, but that it merely strengthens the natural resisting powers of the peritoneum against infection.

Nucleinate of sodium without albumen is prepared by Boehringer & Son, of Mannheim. The dose is 1 gm. or 75 cgm. or 50 cgm., dissolved in artificial serum sterilized by boiling. The injection is given in the gluteal region or in the anterior part of the thorax in the subcutaneous tissue. There is no danger in its use.

The hyperleucocytosis usually does not exceed double the number of white corpuscles in the blood which were present before the injection was given. Sometimes the hyperleucocytosis is more marked, but this has no unfavorable significance.

The method finds its chief application in cases in which there is danger of post-operative sepsis, as in operations on the intestinal tract, and also in those cases in which the conditions for perfect asepsis are lacking, for instance, when one cannot operate in a well-appointed hospital. It is probable that the method will not prove of great advantage in those cases in which the abdominal lesion is not in the digestive tract, provided always that asepsis is perfect; in these cases, of course, sepsis is quite unusual in any event.

THE TECHNIC OF ARTHROTOMY. A REPORT UPON AND DISCUSSION OF ONE HUNDRED AND NINETY-EIGHT CASES.

BY CHARLES F. PAINTER, M.D., AND ANDREW P. CORNWALL, M.D., BOSTON, MASS.

(From the Orthopedic Clinic of the Carney Hospital.)

[Continued from No. 19, p. 730.]

INFECTIOUS ARTHRITIS.

(Female cases.)

CASE 139. J. D., female, twenty, single. Atrophic arthritis. Operation, Aug. 10, 1904.

An incision made over inner side left knee. Capsule of yellowish-blue color and moderately tense. Periarticular tissue very vascular, as in the previous case. Considerable greenish, turbid fluid containing whitish flakes was evacuated. Synovia injected and covered numerous pedunculated outgrowths, one of which was much larger than the rest. Capsule covered with

papillomata. When knee was flexed, the inner, anterior surface of inner condyle showed thinned cartilage, the early stage of an erosion with a definite injection about the center of the area. Edge of cartilage sharp, differing from rest of same in appearance. Papillomata excised and small portion of eroded cartilage removed for pathological examination. Thorough irrigation.

Aug. 18. Stitches removed, wound clean. Fifty degrees of motion in flexion obtained without pain.

Aug. 22. Discharged.

Sept. 2. Knee well.

March 15, 1905. Peroneal spasm in addition to above deformity. General condition improved.

June 29, 1906. Considerable villous thickening of both hands. Left knee shows more thickening and crepitation elicited on motion.

March 26, 1907. Re-entered House.

March 29. Operation.

Incision 3 inches long over outer aspect of right knee, considerable soft material and small fringes removed. Cartilage eroded. No excess of fluid. Pannus over tibial condyle. Wound closed. Hamstrings of left knee were divided by open incision. Plaster from ankle to groin.

April 20. Cast split, to be worn only at night.

April 26. No flexion of knees. Motions are not improved. Discharged home.

Dec. 2, 1908. Joints have improved in function and physical condition.

The knees and all joints except the feet were restored to a condition of usefulness. The feet were lame and sore.

In type, this case was very like the one immediately preceding it, but the result has been very different. It seems to us that probably the explanation of this lies in the fact that the early arthrotomies in this case got rid of the eroding pannus and, therefore, more of the cartilage was preserved.

Case 140. L. T., female, thirty-three, single. Infectious arthritis, metatarso-phalangeal joint, second, left. Operation, Jan. 22, 1904.

Incision 2.5 cm. long over dorsal surface of second left metatarsophalangeal joint. A small purple mass size of pea found overlying articulation. It was boggy with smooth lobulated surface seeming to spring from periosteum on either side of joint. When removed the dorsal surface and sides of the two bones were bared. Periosteum stripped off leaving a rough, pitted bony surface. Tissue removed was evidently the chronic inflamed capsular ligament and synovial membrane. Articular cartilage showed some loss of luster, but no erosion or striation. Head of phalanx (5 cm. excised) and slightly larger portion of metatarsal removed. Plaster cast applied.

Jan. 29. Wound healed. No pain. Discharged.

Jan. 8, 1906. Patient has had similar condition in knee and other joints in same row with above metatarso-phalangeal articulation. Not operated.

Case 141. N. H., female, fifty-five. Operation, Nov. 24, 1909.

Left knee opened by linear incision over inner side. A large amount of thick, yellowish, organised fibrinous material taken out with gauze as curette, some of which was adherent and some loose in the joint. Tincture of iodine applied, then salt solution.

Nov. 28. Patient has been very comfortable since operation.

Dec. 8. Right knee opened on outer side. Material of same nature removed, but less in amount.

Dec. 19. Patient discharged. Motions normal in both knees.

Case 142. A. C., female, twenty-three, single. Operation, Aug. 4, 1909.

Right knee opened on inner side. Capsule of joint thickened and joint contained flocculent, thick fluid and large quantity of organized fibrin, which was broken up with fingers and washed out with salt solution. Entire joint surface curetted with gauze. Posterior wire splint applied.

Aug. 17. Patient has about 35° motion in knee.

Aug. 18. Under ether about 4 oz. of sterile oil was injected under patella and knee flexed to right angle.

Aug. 23. Discharged. Condition very much improved.

Sept. 22. Patella slightly movable. Leg in 15° permanent flexion. Advised baking and massage. Measured for light caliper splint with bend at knee and knee cap.

Case 143. T. H., female, nineteen, single. Operation, Aug. 6, 1909.

Incision made over both outer and inner sides of left knee. Large amount of flocculent material evacuated, also considerable amount of hemorrhagic substance. Joint flushed out with hot salt solution. Posterior wire splint.

Aug. 26. Discharged. Condition relieved.

Nov. 4. Re-admitted to House and oil injection followed by manipulation.

Dec. 17. Voluntary flexion to a right angle. Good operative result. Continue baking and massage. Patella fairly movable, slight capsular thickening only remains.

Case 144. T. T. M., male, twenty-two, single. Infectious arthritis. Operation, Nov. 14, 1904.

Right ankle-joint opened by linear incision 1.5 cm. below internal malleolus. Capsule thick. A small portion was excised and joint again opened by incision below external malleolus. Capsule was less thick on this surface of the joint. A deep-seated varicosity was found but not removed. Wounds closed and foot put up in plaster cast.

Nov. 23. Discharged.

March 15, 1905. Re-entered hospital and spur removed from neck of astragalus; similar exostosis removed from tip of malleolar process of fibula.

March 24. Discharged wearing plaster cast.

Case 145. J. D., female, twenty-three, single. Villous arthritis, wrist. Operation, Dec. 2, 1903.

Longitudinal incision 4 cm. over ulnar side of dorsum of left carpus, beginning opposite styloid process of ulna between tendons of flexor carpi ulnarius and the digital flexor tendons. Synovial sac in view when tendons were retracted contained moderate excess of clear serum. The synovial surface presented multiple tiny villous projections (0.1—0.5 cm. long). These were removed, followed by considerable oozing. Similar incision on radial side dorsum of carpus, inside flexor tendon of thumb. Similar condition of synovia found and treated as above.

Right hand operated upon as above except that radial side was not opened as less swelling was present, but all the synovial surface was curetted from one joint opening.

Wooden splints from elbow to finger tips.

Dec. 9. Stitches removed, wounds clean.

Dec. 12. Discharged. No pain on tentative motion.

Jan. 6, 1904. Flexion of right wrist one third normal; left, one half normal.

Aug. 4, 1904. Referred to Zander room.

Case 146. H. F., male, thirty-one, single. Villous arthritis. Charcot's arthropathy. Operation, Sept. 6, 1907.

Incision over outer upper quadrant of right knee. Capsule moderately vascular. Synovial capsule gray in color, thickened and villous on inner side. Large thick villi are present, especially in the upper outer

portion of the quadriceps pouch and along the margins of the femoral condyle. Excess of fluid, thin and turbid, containing few shredded fibrinous clots closely adherent to the villi. No erosion felt through incision. Wound closed.

Patient has other infectious lesions in spine and ankle.

Sept. 13. Discharged improved to Out-Patient Department.

Sept. 30. Less swelling in knee. Some serous discharge from site of seton left in at operation.

Oct. 23. Some lateral motion in knee. Signs of tabes dorsalis, and in the course of time the joint became completely disorganized after the usual manner in Charcot's joints.

Apparatus was worn for quite a time, and now (1910) the patient has sufficiently good function to tend a drawbridge.

CASE 147. M. C., female, twenty-eight, single. Villous arthritis of right ankle. Operation, July 12, 1905.

An inch and a half incision was made just below external malleolus parallel with the foot. Blunt dissection to astragalo-cuboid articulation. Dark red fringes were seen exuding from the joint. When removed an excess of fluid was evacuated. Another incision made over similar location on foot below internal malleolus, and a similar condition was found in the astragalo-scaphoid articulation.

July 20. Considerable swelling of ankle. Bier treatment instituted.

July 23. Discharged.

CASE 148. B. B., female, twenty-two, single. Tuberculosis, ulnar radial joint. Partial excision. Operation, Dec. 27, 1907.

Incision 8 cm. in length over external condyle right elbow. External portion of capsule protruded slightly. Rotation of radial head accompanied by coarse crepitus and head of bone enlarged and irregular in shape. When capsule was incised, bone was found to be carious. Olecranon process and portion of ulna shaft excised. Head of radius also removed. Condyles of humerus apparently normal and were not disturbed. Synovial membranes also removed as far as possible.

Arm put up in internal angular splint, with slight amount of traction.

Pathological report: "Chronic inflammatory" condition.

Jan. 19, 1908. Wound healed. Discharged.

CASE 149. T. C., male, forty-four. Infectious arthritis. Operation, Sept. 22, 1909.

Incision over inner aspect of left knee. When capsule was opened, a number of villi were found and removed. Few small slightly eroded areas found over surface to tibia and femur. Full extension of leg not obtained.

Sept. 24. Plaster cast applied ankle to groin with leg in as full extension as possible.

Oct. 12. Motion of knee not improved.

Oct. 20. New cast applied and about 10° extension gained.

Oct. 25. Discharged.

Nov. 22. Patient re-entered hospital.

Dec. 1. The usual incision made as for excision of joint. Patellar tendon cut across and knee flexed. Knee showed a large amount of villous growth, and some destruction of articular cartilage present. As little of head of tibia and femur removed as possible. Villi removed from lateral aspects of joint, also quadriceps pouch dissected out. Patellar ligament restored with catgut. Left knee forcibly extended and plaster applied.

Dec. 15. New cast applied.

CASE 150. T. L., male, thirty-nine, single. Operation, Feb. 16, 1906.

Incision 10 cm. long over inner aspect of left knee above patella. Muscles separated down to synovial membrane which was much thickened, and when opened a large amount of serous, straw-colored fluid escaped. Many subsynovial fat tabs found. These were excised, and through a counter incision on opposite side of joint a similar condition was found. These fat tabs were also removed as carefully as possible. Nothing abnormal seen or felt in the cartilaginous surface. Joint thoroughly irrigated with sterile water and wounds closed.

Feb. 18. Knee septic. Patient anesthetized and knee thoroughly prepared. All stitches removed and a bloody fluid containing flocculi with septic odor evacuated. Joint thoroughly irrigated with corrosive. Joint surface presented septic appearance. Drainage instituted and creolin poultice applied.

Culture, streptococcus and staphylococcus.

Feb. 21. Patient failed rapidly and died to-day.

CASE 151. T. M., male, twenty-six. Infectious arthritis. Intermittent hydrops. Operation, April, 1906.

Right knee-joint opened on inner side. Capsule thick and joint contained a quantity of flocculent straw-colored fluid. Many villous formations were found and removed as far as possible. Joint irrigated and closed. Measurements taken each day showed a marked fluctuation in amount of fluid present.

May 18. Left knee operated upon and practically the same conditions found. Several hypertrophic nodes which were situated along the joint line were removed.

June 12. Discharged. Less swelling and intermittency broken up. Joint function good.

CASE 152. J. H., male, thirty-five, single. Operation, Oct. 31, 1906.

Left knee-joint opened over inner side with curved incision. Capsule found greatly congested and infiltrated. Outer side of joint opened in similar manner. Slight excess of fluid, many adhesions broken up and small fatty tabs removed. Joint irrigated with sterile salt solution and wounds closed.

Nov. 7. Knee in 25° permanent flexion.

Nov. 21. Plaster cast ankle to groin; knee in position of 20° flexion.

Nov. 26. Split cast. Can extend leg to within 10° of straight; 45° flexion possible. Discharged.

Jan. 18, 1907. Motion in flexion to 10° of normal. Walks without limp. Continue massage and baking.

CASE 153 (a) J. F., male, thirty, married. Operation, Nov. 21, 1906.

Right knee-joint opened over inner aspect. About 2 oz. of turbid fluid evacuated, containing considerable yellowish, gelatinous material. Synovial membrane hyperemic. Joint thoroughly evacuated and irrigated with hot salt solution. Wound closed, silk seton remaining.

Dec. 5. Plaster, ankle to groin.

Dec. 8. Discharged.

CASE 153. J. C., male, sixty-four, married. Operation, Feb. 4, 1907.

In February, 1906, patient had cartilages removed from both knees without relief. Diagnosis, hypertrophic arthritis. X-ray shows bony thickening of condyles, spurs on femur and patella, some obliteration of epiphyseal markings. Right knee opened through old scar, x-ray interpretations verified. Two small pieces of bone removed from external condyles and wound closed. Plaster cast applied.

Feb. 13, 1907. Discharged improved.

Feb. 19, 1908. Patient died. Probable sarcoma of femur.

CASE 154. J. B., male, forty-three, single. Operation, March 15, 1907.

Right knee opened over inner side. Capsule thickened and vascular. Synovial membrane hypertrophied and

by its redundancy caused numerous folds in the interior of joint cavity. Three of these folds were excised. Joint opened over outer side, same synovial condition found and about the same amount excised. Capsule and bone apparently not diseased. Wounds closed leaving silk seton in lower angle of either wound.

March 25. Discharged. Subsequent return of symptoms similar to that before operation, followed by a gradual improvement at operation.

Case 155. J. S., male, thirty-five, married. Operation, May 5, 1909.

Patient was in hospital Jan. 3, 1908, with diagnosis of tubercular knee. Refused operation and was discharged. For a few months he was able to work without much trouble, but for the last few months he has been obliged to discontinue work owing to the severe pain. Re-entered hospital.

Left knee opened over inner and outer aspects. Slight excess of fluid present of a brownish color. Capsule thick and synovial membrane presented a sluggish inflammatory condition. Under patella a fibrous lipoma was found and excised. Fibrous tags of the same nature found in the quadriceps pouch and on outer side of joint surface. Entire surface curetted with gauze and cavity irrigated with sterile salt solution. Wound then closed.

May 19. Good motion to a right angle, no subjective symptoms.

Discharged.

Case 156. J. S., male, seventeen, single. Operation, Sept. 4, 1908.

Left knee-joint opened over inner aspect. When the thickened capsule was incised, about 2 oz. of straw-colored fluid was evacuated. A velvety pannus covered a portion of the tibial head. This and the interior of the capsule were curetted with gauze and wound closed.

Sept. 25. The same operation was performed on the right knee. Conditions similar to above, but less fluid found.

Oct. 8. Both wounds healed and knees will flex voluntarily to a right angle.

Case 157. T. F., male, forty, married. Operation, Sept. 14, 1908.

Right knee-joint opened over inner aspect. Several ounces of sero-purulent fluid containing fibrin flakes evacuated when thickened capsule was incised. Interior of joint curetted with gauze and wound closed.

Oct. 4. Same arc of motion as before operation.

Oct. 5. Discharged home.

Case 158. E. C., male, twenty-two. Operation, Sept. 16, 1908.

Left knee opened over inner aspect. Capsule thickened. Joint full of sero-purulent fluid containing fibrin, which was evacuated and joint wiped out with gauze and irrigated with sterile salt solution. Wound closed.

Sept. 30. Severe pain has continued. Plaster cast applied.

Oct. 19. Manipulation under anesthesia. Full flexion obtained by breaking up numerous adhesions. About 2 oz. of sterile olive oil injected under patella.

Nov. 4. Discharged home.

Feb. 7, 1909. Slight swelling. Extension limited a few degrees.

July 14. Manipulation under ether and 20° flexion gained beyond a right angle. Adhesions in quadriceps pouch broken up.

Case 159. H. M. M., male, thirty-one, married. Operation, July 7, 1909.

Left knee-joint opened over outer surface. When capsule was incised a quantity of yellowish fluid containing a large sanguinous clot was evacuated. No disease of bone or cartilage was discovered. Joint irrigated and wound closed.

July 15. Discharged. Convalescence uneventful.

Case 160. E. F., male, thirty, single. Operation, July 28, 1909.

Left knee-joint opened over inner aspect. Capsule very thick. Interior of joint covered with organized fibrinous exudate which was very tenacious and could be removed only with difficulty. Similar incision over outer side of joint and same conditions found. Joint wiped out and irrigated, wound closed and light cast applied.

Aug. 13. Discharged to care of his family physician.

Case 161. J. R., male, twenty, single. Infectious arthritis knee. Operation, Feb. 8, 1902.

Joint opened as for excision. A large amount of amber-colored serous fluid evacuated. Synovial tabs found throughout the joint were removed as completely as possible. Cavity then throughly irrigated with sterile water and wound closed.

Posterior wire splint applied.

Feb. 26. Slight amount of fluid in the joint. Motions good, no pain or tenderness. Discharged.

Case 162. I. M. C., male, thirty-nine, married. Osteo-arthritis. Operation, July 11, 1902.

Right knee opened by linear incision over inner aspect. Capsule thick and very vascular. Joint fluid not in excess. Ends of femur presented a squared appearance, due to a redundant growth of fibro-cartilage above it. On under surface of patella, especially near the inner margin, were several bony prominences with corresponding depressions due to osteophytic thickening of the patella. No evidence of inflamatory or maligant growth.

Wound closed and light plaster cast applied.

July 22. Discharged.

Oct. 22. Flexion to 20° beyond a right angle. Complete extension possible.

In this group there is one case of infection, and that had a fatal termination. The patient was not in very good condition and the original polyarthritis was of rather recent origin. In reviewing the case, however, it was impossible to account for the result in any way, though it seemed probable that it was due to some failure in the operative technic.

It will be observed that in this group there were several attempts to preserve motion after arthrotomies by the injection of sterile oil. The writers have been unable to satisfy themselves that the oil has exerted any strikingly helpful influence upon the preservation of motion.

A few cases have strayed into this group that do not belong here on a strictly pathologic classification, and some of the female cases have strayed over among the male group of infectious cases.

In this fourth group are included a number of arthrotomies performed for various reasons upon patients presenting a number of different pathological conditions, or else lesions which are identical to those described in the knee-joint have occurred in other hip-joints where the technic is different from that already described only as the anatomical region necessitated some slight modification.

The following operations were performed upon the hip-joint. In attempting the surgical treatment of lesions of the hip-joint, the problem may be attacked from various positions. Anterior, posterior, or lateral, straight incisions are best. For exploratory incisions the anterior route is

the better; also, for the treatment of acetabular overgrowths or the wiring or nailing of intracapsular fractures. Excisions are best accomplished through the Langenbeck posterior incision.

CASE 163. E. C., female, thirty-four, married. Osteomyelitis hip and stiff knee. Arthrotomy of hip and knee. Murphy's arthroplasty and oil injections. Operation, Dec. 20, 1907.

Linear incision over outer aspect of left thigh above the trochanter. Periosteum over trochanter very thick and adherent to bone. Latter incised and bone removed exposing cortex which was very thin. Cavity found underneath walled off with a hard bone. Contents removed and remaining bony surface thoroughly curetted.

Dec. 27. Wound septic but discharge slight. Sinus dilated and about 3 oz. of thick pus evacuated.

Jan. 29. Left knee flexed under anesthesia. During manipulation a great amount of crepitus could be felt.

Feb. 7. No improvement in knee motions.

Feb. 12. Knee manipulated and ½ oz. sterile olive oil injected into joint under patella. About 40° of flexion obtained without much force, but this could not be preserved.

Feb. 26. Operation. Arthrotomy.

Incision over inner side of knee. Adhesions broken up with finger. Quadriceps pouch obliterated by adhesion with few between patella and femoral condyle. Outer side of joint opened and incision over inner side extended upwards about three inches. Arthroplasty performed and flap sutured to joint capsule on outer side. After closing wounds, except for purse-string suture in outer wound, sterile oil was injected and wound closed.

Plaster bandage ankle to groin.

March 17. About 4 or 5° of motion in joint. Patella free.

April 1. Manipulation and 30° flexion obtained by using considerable force.

April 13. About 20° easily obtained.

April 25. Less motion in knee. Hip still shows slight discharging sinus.

June 1. Slight motion in knee, seems limited by cicatricial tissue. Patient about on crutches.

June 29. Discharged home. Knee very painful beyond 5° motion in flexion. Thin sero-purulent discharge from hip sinus.

Jan. 2, 1909. Re-entered hospital.

Hip has been painful since last operation. Two or more sinuses have been constantly discharging. Physical examination: Leg: flexed with slight adduction, 2¾ inches shortening with very slight atrophy. Probe can be passed down to bone through a sinus over lateral aspect of thigh.

Jan. 6. Incision made upward along track of sinus to posterior surface of the joint. An old fracture of femoral neck was found with lower fragment pushed back giving an abrupt off-set to bone. Firm union seemed to have taken place, but bone was roughened at this point without any evidence of disease. Posterior capsule divided and both head and neck of bone seemed to be normal. A small sequestrum was found, however, on the posterior surface of the acetabulum, which was removed by extending the incision across the buttocks. No bone sinuses found. Wound washed out with salt solution followed by bichloride solution and closed, leaving one large rubber drain.

Jan. 15. Patient has had considerable pain but little discharge until to-day. Reddened area about wound.

Jan. 18. Profuse discharge. Staphylococcus culture.

Feb. 7. Wound irrigated daily with ½ % of formalin solution. Less discharge, but area about the wound remains infiltrated and very tender.

Feb. 8. Condition same. Some infiltration extending up side of os innominatum.

April 12. Condition begins to show improvement.

May 8. Discharge ceased. Patient able to walk about ward with crutches.

May 10. Discharged home.

The injection of oil and manipulation of the knee-joint of this patient, as well as the attempt to procure motion by arthroplasty was a failure.

(To be continued.)

Clinical Department.

SOME CASES OF SUDDEN DEATH DURING PREGNANCY AND THE PUERPERIUM.*

BY HANNAH G. MYRICK, M.D., BOSTON,
Attending Physician, New England Hospital for Women and Children.

THIS subject has been a favorite one with French writers since the time of Philip Pew.[1] In his book, "La pratique des accouchements," published in Paris in 1694, he devotes some eight or ten pages to the prognosis of life in parturient and puerperal women. "When questioned as to the chances, no man ought to absolutely promise any favorable outcome, so difficult is experience. In point of fact, many women, however well attended, however happily delivered, nevertheless cannot escape death. An operator may have acquitted himself perfectly of his duty, his accouchement may have been conducted in the best possible manner, there is needed only one of those unhappy accidents, of which the life of man is full, to cause death, all at once, when least expected. God is master of the life of man; on our part, however qualified we may be, let us promise nothing definite." (Translation from original.)

Brouardel, in 1895, defines sudden death as the rapid and unforeseen termination of an acute or chronic illness which has most often developed in latent fashion. Tarnier considers as dying suddenly those who, suddenly afflicted, succumb a short time afterwards, as, for example, two hours later. Rudaux[2] would include all cases of death which have been preceded by symptoms of short duration.

Among the chief causes of sudden death among pregnant and puerperal women are cardiac disease, embolus, cerebral hemorrhage, grave intoxication, as eclampsia, and hemorrhage from various sources, placenta previa, rupture of the uterus, ectopic gestation or abortion.

The first case in this report is one of cardiac disease. On July 18, 1907, I was called to see Mrs. B., a primipara, aged thirty-four. Her last menstrual period had occurred on Nov. 20, of normal amount and character. Her condition during pregnancy had been good until three weeks previous, when her feet began to swell. Her urine had been examined on May 9 and reported free from albumen. The swelling of the feet had increased and extended up the legs and thighs. There was shortness of breath, pain in the back and inability

* Read at a meeting of the Norfolk District Medical Society, Jan. 25, 1910.

to lie down on account of the abdominal distention and pressure. There had been no headache, nausea or eye symptoms. For the past few days the urine had been decreasing in amount. The bowels had moved regularly. Physical examination showed a large, fleshy woman; abdomen very much distended and projecting far forward in the standing posture. Considerable gas in the bowels. Breasts very large and heavy, resting on abdomen. There was no edema of the face or upper extremities, but the feet, legs, thighs and lower half of abdomen were extremely edematous, hard and brawny. Pelvic measurements all slightly above normal. Breath sounds harsh in the upper part of the lungs, but no râles heard; backs not examined at this visit. On account of the large breasts the cardiac area could not be defined by percussion, but the apex beat was well heard nearly to the anterior axillary line; the second pulmonic was loudly accentuated; the second sound at the aortic area and at the apex reduplicated. No definite murmur heard.

Up to this time the patient had been on ordinary diet and received no medication as she had not considered her condition serious until the increasing swelling of the limbs made it difficult for her to get about. She had been sleeping very little; she coughed a little, but said that she had had chronic bronchitis since an attack of whooping-cough at five years of age. Later a somewhat indefinite history of rheumatism when a child was obtained.

A binder was applied to the abdomen to relieve the dragging and weight. Basham's mixture was ordered and a milk diet. A twenty-four-hour specimen of urine was examined and gave the following: Total quantity, 450 ccm.; dark amber, slightly turbid, heavy sediment; specific gravity, 1,020; reaction strongly acid; albumen, 1.125 gm.; urea, 9 gm.; total solids, 21. Many casts, hyaline and coarsely granular, nearly all with renal cells adherent. As soon as the twenty-four-hour urine had been collected the patient was given calomel followed by a saline.

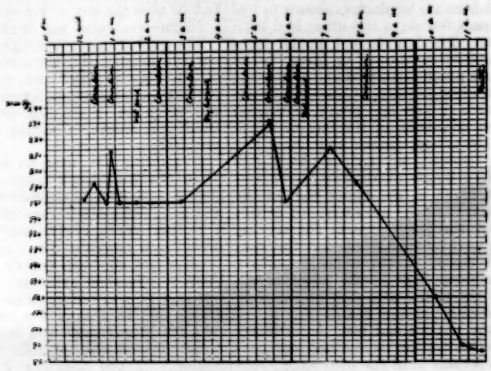
On July 20 a diastolic murmur replaced the reduplication at the apex and was heard of maximum intensity along the left border of the sternum. The aortic second was still reduplicated. The patient was given pil. digitalis, squill and calomel aa gr. i twice daily.

On July 23 the patient felt better, breathing was easier, but there was no decrease in the edema. The heart sounds were stronger and the point of maximum impulse was easily detected 12 cm. from the mid-sternal line. The reduplication was entirely replaced by a murmur.

The urine on July 24 was 600 ccm.; specific gravity, 1,018, strongly acid; albumen, 0.75 gm.; urea, 11.4 gm.; solids, 25.16. There were a great number of coarsely granular casts with renal cells adherent and much renal epithelium. On July 25 the cardiac murmur was very loud along the left border of the sternum. Two murmurs were heard at the aortic area. The edema of the left leg seemed a little softer, but there was no marked improvement and the patient consented to go to the hospital.

She was admitted to the medical ward of the New England Hospital for Women and Children July 25, 1907, service of Dr. Marion Nute. The patient was much more comfortable in the hospital, enjoyed cabinet baths, and slept fairly well, propped up in a chair.

On July 27 at 11 P.M. the patient had a sudden attack of dyspnea, during which she became almost pulseless. The following morning she was much easier, but there was still considerable dyspnea and at a consultation between the medical and maternity departments it was decided that the patient's general condition was so desperate that there was no alternative but to take the risk of bringing on labor prematurely; a diagnosis of twins was made.



The patient had a good night and the following morning was transferred to the maternity ward on the service of Dr. Call as chief and myself as assistant. The patient was extremely nervous and apprehensive. She was given an enema and prepared for induction of labor, maintaining a sitting position throughout the preparation.

It was our intention to insert a bougie into the uterus to start labor pains. With the patient still sitting up I made a digital examination of the vagina and had just inserted a speculum when the patient had a violent attack of dyspnea; the speculum was withdrawn and measures for relief at once instituted, but the dyspnea increased rapidly, the pulse weakened and there was marked cyanosis. A small vein above the right elbow was opened, but no blood could be withdrawn and in a very few moments death occurred. As a fetal heart could still be heard, the abdomen was rapidly opened and two infants delivered by Cæsarean section, — a girl weighing 2,746 gm. and a boy of 2,022 gm. Both hearts beat for three quarters of an hour, but all efforts at resuscitation failed.

A complete autopsy was not performed, but examination of the viscera through the abdominal incision showed chronic mitral and aortic endocarditis with insufficiency, cardiac hypertrophy, effusion into the pericardium and pleuræ, and chronic passive congestion of liver, lungs, spleen and kidneys.

The second case is one of eclampsia. Mrs. W., primipara, aged twenty-five, was admitted to my service at the New England Hospital March 7, 1909, in an unconscious condition. A convulsion had occurred that evening at 10.15 P.M. and a second one in the carriage on the way to the hospital, which she reached at 11.30 P.M. Examination showed the cervix taken up and the os admitting one finger. Blood pressure, 180. The fetal heart could not be heard. Bromide and chloral were given per rectum and the patient put at once into a hot wet pack. Dilatation progressed rapidly, but eight more convulsions occurred between midnight and 6 A.M., the blood pressure varying from 180 to 230 mm. Morphine, gr. ¼, was given shortly after 6 A.M. and at 6.30 a macerated child was delivered by low forceps. There were no more convulsions till 8 A.M. The blood pressure at this time was 190 mm. A second injection of morphine was given and a hot blanket pack. The patient was very quiet in the pack and the blood pressure gradually fell. The breathing became quiet and natural, pulse good and the patient seemed much better. About 10.45 A.M. it was noticed that the left pupil was much larger than the right and the blood pressure began to fall rapidly (see chart). Other than this the general condition seemed quite satisfactory. A consultation was held as to the desirability of stimulation on account of the rapid fall of pressure, from 195 to 90 mm., but the pulse-rate was good and regular, breathing quiet and natural, and a favorable outcome seemed fairly to be expected. At 11.52 A.M. the patient suddenly became very cyanotic and death occurred in the course of a few moments.

No autopsy was permitted. Although in this case the patient had had eleven convulsions there had been none for nearly four hours before death, the stertorous breathing had been replaced by quiet and natural respiration and the whole appearance of the patient was such as to convince those who examined and watched her that her

Blood pressure chart, Mrs. W.

sudden death was due to either embolus or cerebral hemorrhage. Rudaux calls attention to this as a cause of death in certain cases of eclampsia, stating that the albuminuria causes alterations in the vessels, that labor and especially convulsions increase the vascular tension. Balika [4] also reports a case where after twelve convulsions the pulse was only 64–68, labor pains good and patient doing well; three hours later sudden death occurred. Autopsy revealed extensive cerebral hemorrhage.

My third case is one of cerebral hemorrhage. Mrs. C., aged twenty-one, para II, was admitted on my service at the New England Hospital May 19, 1909. Her first child was stillborn at seven months. The present pregnancy was within a few days of term, the last menstrual period having occurred on Aug. 22. She was not in labor on admission, but thought that the child was dead as she had not felt life for some time. The urine contained a small amount of albumen. Pains began soon after admission and the labor was uneventful, terminating in the birth of a stillborn child weighing 3,340 gm. For two days following delivery the patient felt nauseated and had some difficulty in voiding urine, but from the third day the puerperium was normal. On the tenth day the patient sat up for half an hour, and the following day for an hour in the morning; towards evening of this the eleventh day she complained of headache and her temperature reached 99.4°. Next morning the headache continued and the temperature was 100.6. At about 10 A.M. she was seized with a convulsion; the twitching was practically limited to the left side and especially the upper extremity; the tongue was bitten, but there was no twitching of the face muscles. This convulsion lasted six minutes. Two hours later there was a second attack lasting four minutes; twenty minutes later there was twitching of the left arm, but consciousness was retained. The blood pressure was only 100 mm. A catheterized specimen of urine showed a very slight amount of albumen. During the afternoon and evening the patient was quite comfortable and talked a good deal. In the early morning of the following day she became restless and at 5.05 A.M. twitching of the left side of the body occurred, especially the arm; the face muscles were not involved. The face was flushed, eyelids swollen, and the eyes seemed a little more prominent than previously. The convulsive twitching increased in intensity, with but momentary intermissions, and by 1.30 P.M. the muscles of the left side of the face and both eyes began to twitch; the head was drawn to the left. In spite of the violent movements the patient appeared to hear when spoken to. The temperature rose during the morning, reaching 105.6, where it remained through the afternoon. At 3.30 P.M., the convulsive movements of the left side still persisting, the right leg became paralyzed. At 8.35 P.M. the left arm stopped twitching for the first time in fifteen hours. At 9.45 the twitching of the left side of the face and left eye ceased. The lips and finger tips were cyanotic. The pulse could not be felt on either side, but the heart was beating eighty times per minute; the body was hot and moist, the right leg much mottled, respirations sighing. Death occurred at 10.24 P.M. The temperature shortly before death reached 108.6°.

Dr. James J. Putnam saw the case with me during the forenoon and thought it undoubtedly one of cerebral hemorrhage. No syphilitic history could be obtained, but the history of a previous pregnancy ending in the premature delivery of a stillborn child, together with the second stillbirth, is certainly suspicious. Dr. Putnam was inclined to think that the hemorrhage was caused by changes in the vessels due to pregnancy rather than to any specific influence. A history was obtained of partial paralysis of the right leg following an attack of fever at three years of age; the fever was said to have been scarlet fever, but on closer questioning of the patient's mother it seemed highly probable that it was really acute anterior poliomyelitis. A complete autopsy was permitted and the following condition within the brain was found (Dr. L. J. Rhea):

Dura strips easily from the pia. The great longitudinal sinus contains a friable, pale, grayish-red clot which in places is adherent to the vessel wall. The pial vessels are generally enlarged and contain a clot; in some this is definitely adherent to the vessel wall. Beneath the dura covering the left lateral hemisphere is a thin diffuse layer of blood clot; anteriorly this clot covers the brain completely; there is a similar lesion, though much less marked, over the right hemisphere. On section the brain surface on the left side shows no gross lesions. About the center of the brain substance of the right hemisphere, and situated just posterior to the fissure of Rolando, is a fairly well-circumscribed

dark-red blood clot about 6 cm. in diameter; the brain substance immediately around it is soft and generally light red with small bright points throughout. Vessels at the base of the brain and skull are normal. Anatomical diagnosis: Cerebral hemorrhage. Thrombosis of longitudinal sinus. Subdural hemorrhage.

The reported cases of cerebral hemorrhage during pregnancy and the puerperium are comparatively few. Jardine [4] reports one occurring in the eighth month of a third pregnancy; both other pregnancies had resulted in the birth of a stillborn infant at seven months. The patient during this third pregnancy had been exceedingly nervous and apprehensive lest this child should also be lost. The attack began with sudden loss of power in the right hand; the face twitched and was drawn to one side, and the patient became unconscious. On admission to the hospital ten hours later a large quantity of albumen was found in the urine. Death occurred during labor three days later. No evidence of syphilis could be found, but the history of the previous labors was suspicious. Rudaux also reports a case of death sixteen hours after delivery, the symptoms in this case lasting six hours. There was no actual hemiplegia, but shaking of the upper limbs, followed by contraction and finally relaxation. There was Cheyne-Stokes respiration, increasing coma and death. Autopsy revealed a large cerebral hemorrhage.

In connection with the first case in my series an interesting question arises whether the fatal attack of dyspnea was due to a culmination of the patient's extreme nervous apprehensions, or whether it was precipitated by reflex nervous action resulting from the vaginal examination. McClanahan,[5] in enumerating the causes of sudden death in pregnancy and the puerperium, says, "Among the rare causes of sudden death should be mentioned the reflex nervous shock resulting in some inexplicable way from vaginal examination or manipulation." Rudaux also refers to it as one of the causes of sudden death, and Mihalkovits,[6] Frigyesi [7] and Von Seuffert [8] report cases of death during or immediately following examination.

The question of performing post-mortem Cæsarian section in such cases is an open one. Some authors advise against it on the score of the shock to the patient's family and the doubtful chance of obtaining a living child. Weiswanger,[9] indeed, reports a living child delivered by Cæsarean section nineteen minutes after the death of the mother, but such cases are phenomenal. Many recommend rapid extraction per vaginam in the case of multipara, as the tissues are relaxed and easily dilated immediately after death. Von Seuffert has tabulated the reports of various writers to determine the number of living children delivered by post-mortem Cæsarean section. In his first table, out of 778 cases reported by five different writers, a living child was obtained only nine times. His second table, from more recent statistics, gives 81 cases reported by three different writers with 40 living children; the improved results he attributes to better methods of resuscitation. He gives three cases of his own; in the first the infant was resuscitated with some difficulty; in the second case, one of cerebral hemorrhage, the infant was dead and in the condition of rigor mortis. His third case was one of eclampsia and brain tumor, a twin pregnancy; the hearts beat for thirty and forty minutes after delivery, but neither infant could be resuscitated, a somewhat parallel case to the one I have reported.

Medical Progress.

RECENT PROGRESS IN OPHTHALMOLOGY.

BY MYLES STANDISH, M.D., BOSTON,
AND
EDMUND W. CLAP, M.D., BOSTON.

TRAUMATIC RING-SHAPED OPACITY OF THE LENS.

Vossius, in 1903, first described two cases of ring-shaped opacity of the anterior surface of the lens following traumatism and disappearing in a few weeks. Now 17 cases are on record, 15 of contusion and 2 of perforation of the eyeball. The opacity is situated in or on the anterior surface of the lens at the center, and is about the size of a contracted pupil. It is usually annular, but may be incomplete, made up of dots or of fine lines, and the ring may be of varying width. In some cases the opacity was disk-shaped, of fine dots closely aggregated at the periphery, giving the effect of a ring at first sight. Gifford reports one with fine stippling all over the anterior surface of the lens both inside and outside the ring, and Löhlein speaks of disk-like opacity with ring-shaped accentuation. Hoeg's case showed very slight opacity within the ring and a few radial opacities towards the lower periphery of the lens. The opacity is of a light gray color, in some cases not visible by reflected light, but darker by transmitted light, and in some cases has a brownish color or the gray dots are mixed with brown ones, suggesting pigment left by posterior synechiæ. The ring is best seen by dilating the pupil. Hyphema was present in many but not in all the cases, and other results of contusion, as abrasions and infiltrations of the cornea, mydriasis, posterior synechiæ, chorioidal rupture and hemorrhage into the vitreous. The opacity clears up in from one to six weeks, usually in three weeks, without in itself affecting the vision. While usually circular, the opacity in one case with prolapse of iris was ovoid, corresponding to the pear-shaped pupil. The opacity probably occurs immediately at the time of the traumatism or within a very

short time, as it has been found within a few hours of the accident and has always gradually lessened, never increased, after it was first observed. In most cases the injury was caused by a slight or moderate blow. Vossius thought it was due to pressure of the pupillary edge on the anterior capsule of the lens, and the brown discoloration was iris pigment. He supposed the cornea to be suddenly forced in against the iris, pressing it on the lens round the edge of the pupil and causing some adhesion of pigment and a degeneration of the epithelium of the lens capsule, and this view was generally accepted till Hoeg called attention to the impossibility of the cornea coming into contact with a sufficiently large area of lens and iris to make the ring without rupture of the cornea or iris. Also the blow would have to be exactly in the center of the cornea and be due to a small body, and this would make more of an impression at the center of the anterior capsule and, therefore, not in the form of a ring. But these rings are caused by objects varying in size and striking the eye from different directions and usually without rupture of the cornea or iris. Gifford reports a typical case caused by a glancing blow of a small piece of copper at the inner periphery of the anterior chamber. Steiner's case was caused by a bullet wound in the orbit compressing the eye from behind without directly injuring it. Hoeg and Gifford agree that the appearance is undoubtedly due to degenerative changes in the anterior capsule with some pigment from the iris in some cases, but the cause is the sudden increase of pressure in the anterior chamber pushing the iris against the lens.

CATARACT EXTRACTION IN THE CAPSULE.

The past year has shown a great development of interest in the extraction of cataract in the capsule as practised by Major Henry Smith, Jullundar, India. Several surgeons have gone to India and done the operation under his personal instruction, doing one to four hundred extractions apiece, so that their reports and opinions are worthy of attention. The early hostility to this operation is passing away as we find that Smith's technic has not been used by other operators who have supposed they were doing his operation, and it appears now that Smith has made an important contribution to ophthalmology, even if his operation does not finally supplant the capsulotomy operation in all but certain cases. It will be admitted that removal of the lens in its capsule is a vastly better procedure than the leaving of the torn remains of capsule and fragments of lens substance so apt to cause delayed healing, iritis and infection. The question is, Can extraction in capsule be done safely without frequent loss of vitreous by an operator of average experience and ability? Smith has done 22,000 operations, 20,000 of them in the capsule by his method, and has acquired a high degree of skill in it. He has modified his procedure from time to time, trying various expedients through a large series of cases, and now for two years he has followed his present method without change. He extracts all sorts of senile cataracts, simple or complicated, but not juvenile or congenital, as here it is almost impossible to dislocate the lens. A trained assistant is necessary, and his skill is as important as that of the operator. He must know just what to do as each emergency arises, and the avoidance of loss of vitreous is chiefly due to his manipulations. The corneal section is made with a speculum in place and the eye held with fixation forceps. The knife starts well back in the sclerocornea and the counter-puncture is made in a corresponding position in such a way as to have the section include nearly one half of the circumference of the cornea. The cut should be made if possible with the one thrust across of the knife or certainly completed with the drawing back, no sawing, but a clean cut, bringing the knife out in the cornea nearly at a right angle to the surface so as to have no overriding which may cause unnecessary astigmatism. Iridectomy may or may not be done. Perhaps it is best for beginners to make a small one. After the iridectomy, the speculum is removed and the assistant takes charge of the lids, drawing down the lower lid by the thumb of the left hand and lifting the upper lid up away from the eye on a large strabismus hook held between the thumb and first two fingers while the third and fourth fingers press firmly on and draw back the brow, giving a complete control of the lids and preventing the patient from squeezing out vitreous. The eye is now relaxed at the bottom of a pit in which the operator must work, but where there is very little tendency for the vitreous to extrude. The eye may now roll up or into whatever position the patient chances to put it, though this is usually up. Smith does not give the patient any commands as to what he shall do, and operates with the eye in any position, not speaking to the patient at all and, indeed, the American operators who did so many operations in India report that they could not have made their patient understand even if they had wished to. Next the blunt point of a strabismus hook should make firm pressure over the lower edge of the lens, viz., on the lower part of the cornea, directed back towards the optic nerve and then steadily maintained. As the lens yields it must be followed up to keep it in the wound and prevent the escape of vitreous, so the hook folds the corneal flap up under the escaping lens, letting up as soon as the lens is out. Intumescent lenses may be made to turn over by pressing on the lower edge backwards and then down towards the patient's feet till the suspensory ligament ruptures, when the hook follows up as the lens turns over and comes out lower edge in advance and posterior surface upward. Should vitreous present, it may be held back with the spatula in the left hand and the lens be delivered sliding up and out on the concave surface of the spatula. The assistant still controlling the lids, the iris can be deliberately replaced and the eye closed and bandaged and not redressed till the eighth day, as iritis is not to be feared after this operation. Rupture of the capsule during expulsion of the lens is a serious accident as vitreous

usually is lost in attempting to pull out the remains of the capsule, and iritis and infection may follow leaving the capsule behind. Removal of the ruptured capsule should be tried, but if not accomplished a needling may be done later if necessary. Smith has less than 5% vitreous loss, and his pupils report about 5% of losses of vitreous, but this showing can be made by beginners only under skilled guidance. Numerous authors favor the operation especially for immature, slowly ripening cataracts, where our present methods mean a long wait for the patient. Savage has devised an instrument for tearing the suspensory ligament before trying to express the lens, and numerous modifications are described by English and American authors. The future of the operation in the hands of other operators than Smith and on other races than the Indian will be decided only by a large series of cases.

SYMPATHETIC OPHTHALMIA.

One of the many unsolved problems of sympathetic ophthalmia is to account for the cases, few but undoubted, which occur with sarcoma in the first or exciting eye, without any wound or perforation. Meller discusses this subject, and as our knowledge of sympathetic ophthalmia has made advances, especially along pathological lines, in the last few years, it is worth while to give a summary of what we know certainly about it. Sympathetic ophthalmia is a specific affection of the uvea, characteristic histologically. The uvea of the first eye forms a granulation tissue of lymphocytes, epithelioid cells and giant cells, as specific an infection as tubercular or syphilitic infiltration of the uvea, caused by a definite virus. Sympathetic ophthalmia is completely distinct from other forms of uveitis, whether they spontaneously arise or occur after injuries. Fuchs showed how we can distinguish a sympathizing or an exciting infiltration from endophthalmitis whether one is present alone or both are present at the same time. Sympathetic infiltration always starts in the uvea and especially in the choroid, which is never spared entirely. Though most authors assume the necessity of an external opening (operative, accidental, or from perforating ulcer), there is now no doubt that cases occur without trauma, and the infection might, of course, be endogenous even in the cases of external opening, which may change the resistance of the eye. Meller's present case is one of sarcoma leading to blindness of one eye seven years before the second eye was attacked by typical sympathetic inflammation. The sarcomatous eye from necrosis of the growth had had a severe plastic inflammation, but, so far as the uvea was not destroyed by the sarcoma, sympathetic infiltration was clearly present. As no signs of degeneration were present, the duration of the exciting infiltration could not have been long. The histological examination was very thorough, and a complete series of sections of the whole globe showed that there was no scar of any perforation, recent or old, viz., no communication of the eye with the outside. The sarcoma had recently started to grow again, and there was some necrosis, which possibly accounts for the starting of the sympathetic process. This case, with thirteen collected by Schirmer and three by Fuchs, comprise the authentic reported cases of sympathetic inflammation following intra-ocular sarcoma, and twelve of these cases had no perforation of the globe, viz., the sympathetic infection must have been endogenous. If the germ, then, may circulate in the blood, why do we not get this type of ophthalmia after infected wounds of other organs of the body? A previously sound eye is not subject to the exciting inflammation; always the uvea must have suffered some injury or infection in order to become the site of this specific infection. Too severe an endophthalmitis (especially a panophthalmitis), on the other hand, is unfavorable to the development of sympathetic. In these cases of sarcoma the uvea has been the seat of an inflammation not of sympathetic nature first, or there has been direct injury of the uvea from necrosis of the growth, showing that the ground must be prepared. All observers have been surprised that a very small proportion of all eyes enucleated as in danger of giving rise to sympathetic ophthalmia really have shown the characteristic infiltration of an exciting eye, but if the infection be an endogenous one, this fact is not surprising; the eye did not have the exciting infection, but had conditions favorable to it. It might not begin for years, but when it did, then the other eye shortly incurred the infection, but an enucleation short of the time of the endogenous primary infection would show nothing of the sort. This would explain the sympathetic ophthalmia coming on many years after the injury to the first eye, and, indeed, in these old eyes the exciting infiltration is always a fresh process. Fuchs has shown that the infiltration, even in the exciting eye, attacks mostly the posterior part of the uvea and in numerous separate foci, afterwards fusing, but not starting and infiltrating in continuity,— all this suggesting an endogenous origin, — the process beginning from the vessels of the choroid much in the way that miliary tubercles of the choroid arise when the infection is endogenous. Sympathetic ophthalmia following sarcoma of the exciting eye is a pure and uncomplicated experiment given us by nature and indicates that even in the usual cases following injury to the first eye the origin of the sympathetic may be endogenous.

S. Weigelin, in an exhaustive and able monograph, reports a complete histological examination of 41 eyes; 17 primary eyes in undoubted cases of sympathetic ophthalmia; 8 eyes in doubtful cases; 4 eyes causing sympathetic irritation in the other eye; 2 sympathizing eyes, and 10 eyes with traumatic iridocyclitis. Interesting is the author's collection from the literature of 1,150 cases of perforating injury, of which only 12 gave rise to sympathetic ophthalmia, — about 1%. His summary is worth quoting: "In every case of true sympathetic ophthalmia the characteristic typical exciting infiltration of Fuchs was found in the first eye." "In all cases of traumatic iridocye-

litis in which the second eye did not have sympathetic inflammation, there was found a different anatomical picture having only a distant resemblance to the exciting infiltration." "In cases of doubtful sympathetic inflammation the pathological examination was able to decide the question." "The examination of two sympathizing eyes showed anatomical conditions similar to those in the exciting eye." "In one case of spontaneous iridocyclitis of both eyes, in the first attacked was the typical picture of sympathetic infiltration." "Admitting that we have now a characteristic pathological picture to be certainly distinguished from that of traumatic iridocyclitis, there are a few cases of spontaneous iridocyclitis not to be distinguished from sympathetic ophthalmia except that they are not preceded by a perforation of the eyeball." Meller's theory of the endogenous origin of the sympathetic virus would account for these cases. Wagenmann gives a complete pathological report of a case of sympathetic ophthalmia following extraction of a dislocated lens. An insidious fibrinous inflammation followed and five weeks after the operation the second eye gave the first subjective symptoms. Two days later the first eye was enucleated, and three days after that the second eye clearly had sympathetic inflammation. Twenty-three days later the patient (forty-eight years old) died from cerebral hemorrhage and both eyes were examined and sectioned and an exactly similar type of infiltration was found in each eye corresponding to that found by Fuchs, Schirmer, etc., in every case of sympathetic ophthalmia, as well as the endophthalmitis of Fuchs in the first eye.

OPERATIONS FOR GLAUCOMA.

The last few years have seen several new or modified revivals of old operations for glaucoma. Iridectomy is satisfactory for acute cases and for those with persistent increase of tension, but not as useful in simple chronic cases and in those with the tension slightly elevated at times. Heine five years ago devised an operation that he called cyclodialysis which consisted in separating the ciliary body from the sclera for a short distance so as to break into the anterior chamber through the ligamentum pectinatum, making a communication between the anterior chamber and the suprachorioidal space. This operation seems to have made a place for itself. Elsching reports 110 operations in detail and prefers it to iridectomy in some cases, especially those without inflammatory symptoms. Drainage from the eye by a permeable scar has been the object of several old operations. De Wecker's sclerotomy aimed at a filtration scar without inclusion of the iris, and many varieties have been introduced, such as the operation of Herbert, who cuts a little tongue of sclera near the cornea, under a conjunctival flap, with the purpose of getting a filtering cicatrix. Then another series of sclerotomies have incarceration of iris in the wound as an essential part. Holth makes a flap incision in the sclera near the limbus, then an iridectomy is done and the iris left entangled in the subconjunctival scar. The dangers of sympathetic ophthalmia and infection loom over these operations. Lagrange's operation of sclerecto-iridectomy is done by cutting a scleral flap as near the root of the iris as possible and then cutting a sliver of sclera from the anterior lip of the wound so that an oval gap is left under a conjunctival flap. Iridectomy may be done at the same time. This operation may leave a fistulous cicatrix. Herbert also does a delicate operation consisting in cutting out a wedge-shaped piece of sclera attached only to conjunctiva so that when it is replaced it may shrink and leave a filtering space about it. A trephine operation for lowering tension was done by Argyll Robertson and others long ago, but several such procedures are recent. Fergus and Elliot each do a trephine operation to make a permanent opening for drainage; Fergus also adds what is practically a cyclodialysis. Verhoeff has devised an ingenious punch to cut out a piece of sclera with a minimum amount of traumatism, leaving a clean round hole 1 mm. in diameter. He does a small buttonhole of the iris under the hole to avoid prolapse or incarceration of the iris. Ballantyne, in reviewing these operations, concludes that it is clinically possible to produce a scar through which fluid within the eye will exude either by microscopic channels or by a small fistula. Histologically the material is too scanty as yet to decide with how much certainty we can get a permanent filtering scar in a given case, but clinically and histologically the filtering cicatrix is a reality. Further, he thinks that all these operations have a sphere of usefulness.

Reports of Societies.

THE AMERICAN CLIMATOLOGICAL ASSOCIATION.

WASHINGTON, D. C., MAY 3, 4 AND 5, 1910.

[Concluded from No. 19, p. 739.]

DR. JAMES ALEXANDER MILLER, of New York, read a paper on

THE TUBERCULIN TREATMENT OF PULMONARY TUBERCULOSIS IN OFFICE AND DISPENSARY PRACTICE.

He classed present medical opinion as to tuberculin as follows: Those who are still influenced by early antipathy to tuberculin, caused by its misuse and

fostered by the denunciation of Virchow; second, those who view it as a short cut to diagnosis and treatment which will spare the necessity for more laborious and painstaking methods; and, last, those who believe strongly in the value of tuberculin, but have come to realize its limitations so that it is welcomed simply as one more valuable aid to be used in careful conjunction with other methods. The last class is growing rapidly. The chief value of tuberculin is that it causes a specific response in some of the vital reactions of the body which are closely associated with true immunity, e. g., opsonins, agglutinins and precipitins; and in the additional toxin tolerance which is also, perhaps, a real toxic immunity. There is also a slight local hyperemic reaction which seems to be important. But this method of toxic tolerance, or gradual habituation of a patient to the hypodermic administration of increasing doses of tuberculin, is the chief element in the cure. No one of the ordinary preparations of tuberculin seems to possess advantage over others. In its administration the aim should be to produce no general reactions. The time element in treatment is more important than the absolute dosage, the latter varying with every case, and the former never less than six and often more than eighteen months. The method is quite as applicable in dispensary and office treatment as to those in sanatoria.

Dr. Herbert Maxon King, of the Loomis Sanatorium, read a paper on

VACCINE THERAPY IN TUBERCULOSIS AS APPLIED IN INSTITUTIONAL PRACTICE.

This consists in (*a*) the treatment of the tuberculous infection itself by some one or more of the tuberculins, and (*b*) the treatment of the pyogenic infection by the specific bacterial product indicated by the character of the secondary infection. Autogenous tuberculins are not generally employed, as there is no special advantage in their use.

At the Loomis Sanatorium two classes of patients are advised to take tuberculin, viz., (*a*) the class of incipient cases which have been under observation for a sufficiently long time to justify the belief that they are not progressive and are without fever or other evidences of a marked general toxemia, and (*b*) that class of more advanced cases, presenting evidence of "arrested" activity, who have been for some time without material change in their condition, either local or constitutional, but who still have cough and a bacillary sputum. If given in febrile cases, the results have always been negative. The one demonstrable and constant result of the suitable use of tuberculin is tuberculin immunity; this is the first consideration and the line of pursuit throughout the whole course of treatment.

Dr. King believes that a suspension of B. E. in B. F. comes nearest to the ideal choice; but B. E. has the disadvantage of producing at times, and without premonition, rather disagreeable reactions and requires, perhaps, more care in dilution than some other varieties. Dr. King gave minute directions as to dose and interval and insists on individualization in treatment. He endeavored for a long time to utilise the opsonic index as a guide to tuberculin administration, but abandoned the method as impracticable. He insists on comparative rest on the day of the injection and strict rest for thirty-six hours afterward; the injections are given in the late afternoon. This is easily controlled in sanatorium practice. Remarkably good results were obtained in laryngeal lesions where focal, not general, reactions are frequent. A typical case was cited. Dr. King then took up the treatment of secondary pyogenic infections by autogenous vaccines. This method is applicable in cavity cases with high fever which do not yield to rest in bed. The technic was described. The emulsion is made and sterilised at 60° C. and standardised. The initial dose is from twenty to forty million, which, if no counter-indications arise, is first repeated and then increased at the rate of 100% until from one hundred to two hundred million is given at intervals of from two to ten days according to circumstances. No untoward effects have been noted. Subsequent temperatures have never been noted as being higher after the injections.

Dr. Walter A. Griffin read a paper on the

USE OF TUBERCULIN AT THE SHARON SANATORIUM.[1]

It has been in use there for diagnostic purposes for eight years, and as therapeutic measure for five years. One hundred and nineteen cases have been tested by it, and 36 have had it in the way of treatment. Of the tested cases, 4 are known to have died, but only one of these died of tuberculosis, and this was a nurse who left the sanatorium in good condition and worked as a nurse for eight years. She died of hemoptysis. The usual procedure was to give 2 mgm. the first time; followed, in case no reaction occurred, by 5 mgm. and 10 mgm. In all cases either old tuberculin or bouillon filtrate has been used. These products are probably safer than some of the others and the results seem as good as with any other tuberculin.

Dr. Randall said that the applications of opsonic treatment by vaccines to diseases of the ear have been too limited and carried on by too few investigators to have reached definite results. Hardly a hundred individual cases are recorded, and while these are encouraging, especially to enthusiasts, there are too many loopholes for any estimate of them to carry conviction to clear minds. The permanence or uniformity of success which should distinguish a monumental improvement in therapy cannot yet be considered established, while some of the reports are open to suspicion of being none too well posted, or else too pessimistic as to the older measures. Closer scrutiny of the instances of its employment will probably give greater confidence in the possibilities of the method, and it is hoped that this joint consideration of the subject will serve to crystallise into more available shape its practical applications, and that growing experience will show more frequent realisations of the hopes and claims of the enthusiasts.

DISCUSSION OF VACCINE THERAPY.

Dr. J. Solis Cohen, Philadelphia: I have had a very prolonged experience with tuberculin; for thirty years I was consulting physician for consumptives, and gave the first injection of tuberculin in Philadelphia before my class at the Jefferson Medical College upon a patient with advanced tuberculosis of the larynx in the early eighties. Ten years ago I heard that that man was well and was a successful ranchman in Wyoming. I have not heard from him since. Fifteen or sixteen years ago a man came to me from the South with extensive ulceration of the larynx. He was placed under treatment and after a number of months his disease was arrested. Two years afterward his life was insured for $100,000 in the Mutual Life Insurance Company of New York. In that case not only was the injection given hypodermically, but the tuberculin was rubbed over the laryngeal surfaces, and he took rectal injections himself every night. There is no doubt that in this case there was a great success. I know of several other patients still living at different periods

[1] See Journal for July 28, 1910.

of five to fifteen years or more, and doing well. The tuberculin that I have used has always been the old tuberculin of Koch, except when we were unable to get it, and then other forms were used, but did not appear to present any special advantages. These injections were used very much as the last two speakers have described, beginning with minute doses and gradually increasing them, and studying the patient rather than the disease.

I would like also to state something else. When I began the study of medicine some fifty-five years ago, I studied under a preceptor, as was customary at that time; and it was the custom then to apply fly blisters as near as possible over the site of the lesion of phthisis. We knew nothing of the bacillus tuberculosis at that time. Many of the cases improved, and since the tuberculin and serum treatment have been applied I have come to the conclusion that possibly the absorption of some of the serum raised by these blisters was beneficial in the same manner as the serum when injected under the skin, and, acting on that principle, it has been my custom with many of my patients to blister the chest below the clavicle, taking care that the blister shall not burst, so that the patient's own serum shall be absorbed on the same principle as the autogenous methods. I do not often attend these meetings, but would like to give my testimony as to the advantage of this treatment in properly selected cases and under proper precautions.

DR. V. Y. BOWDITCH, Boston: I can rank myself in the first class spoken of by Dr. Miller who tried it as soon as it was given to the public and after a few cases gave it up. I abandoned it after a few cases, largely influenced by the statement that there was danger of causing disseminated tuberculosis, and for many years I had a great repugnance against it. Finally I felt that I was doing injustice to many patients who might possibly be having treatment withheld which would do them good. Feeling with Dr. Griffin that certain cases had been going on under dietetic and hygienic treatment and making no progress, we agreed to give them the benefit of this treatment, and did so; the results were so startling that we felt justified in going on. To make a long story short, we now, in addition to beginning with cases which have not been doing well, begin on the incipient cases also. My position now is that of being greatly impressed with the tuberculin.

DR. WALTER A. GRIFFIN, Sharon, Mass: Taking up the consideration of Dr. Bowditch's last remarks, I would like to say something further about what we have been doing at the Sharon Sanitarium. We began with one case which had been to us before and under hygienic treatment for seven months, and had been discharged as an arrested case. In seven months she was back again, and although we kept her under hygienic treatment for five months she made no improvement beyond a certain point. It was this case which Dr. Bowditch said would be worth trying with tuberculin. We gave her treatment for five months, at the end of which time the tubercle bacillus had disappeared, and now she has been doing her laborious work in the kitchen. I saw her within a month past and went over her chest, and found her in very good condition.

The second case was similar in that the patient had been with us for several months and was not only not doing well, but was losing ground; the cough was increased and there were beginning objective signs in the larynx. She had tuberculin treatment for seven months, and it is her boast how that she has been out nearly five years and has not seen a doctor at any time within that period. We have now to report on 28 cases which have had tuberculin treatment at Sharon and have been discharged for more than a year. Of these 28 patients, 6 have died; 2 were really too far advanced to warrant advising tuberculin, but took it at their own request; 4 others were advanced cases and were given tuberculin because it did not seem possible that they could improve under ordinary hygienic treatment, and it seemed to be a forlorn chance for them. Four others are not doing particularly well. They were all advanced cases, but I am afraid they are going down hill. This makes 18 cases out of the 28 which are doing well, and this seems to be a comparatively good record when all of the cases with the exception of 3 were more than incipient, and all but the 3 had tubercle bacilli in the sputum. These 3 were given treatment for special reasons. It is known that the tuberculin will do no harm, and frequently will do good.

DR. NAGLE, Boston: I do not want to be too enthusiastic about vaccine therapy, but I believe it is a valuable adjunct in treatment. I wish, however, to emphasize the importance of the proper preparation of the vaccines and the method of giving them.

DR. C. L. MINOR, Asheville: The point is whether or not tuberculin should be used on every patient or only on selected cases. The tendency of some is to use it on every case. I have been slowly brought around from skepticism to belief in tuberculin, granted that it is a selective use. I do not believe that a patient should be put on tuberculin as long as he is making progressive and steady improvement, but for those who have done well up to a certain point and then reach a stage of chronicity when they go neither forward nor back, I believe that tuberculin is a valuable aid. When used in this way I have used it with wonderful effects. I think if the idea went out that it was applicable to all cases, much damage would be done by it. To show how dangerous it may be when used promiscuously, I would like to cite the case of a boy seen by a doctor after he had been in the hands of a quack. The boy had incipient tuberculosis, and the quack started at once on daily injections of tuberculin; the boy began to have reactions, and the quack continued the treatment until the boy became a hopeless case. Men with dangerous and uncontrolled enthusiasm might do something of the same kind with it.

I believe that it is valuable when used selectively, but all cases do not do well on it, and some cases with the greatest care are unable to take it. I would advise great care in the selection of cases for this treatment.

DR. W. B. JOHNSON, Paterson: The question is developing along the lines of tubercular disease and tuberculin. I would judge that tuberculin has been successful in a number of cases, but the important consideration to the otologist is what can be done with the autogenous or stock serum for the destruction of bacterial elements which enter into the diseases we are called upon to treat. I have followed serum and vaccine therapy for a number of years. One case of sarcoma of the pharynx I treated with the Coley serum with success — it was one of the few cases that were successful. I have also used the stock vaccines and serums, and while it seemed as if in some cases life was prolonged by the use of the serum and vaccine, it was not with me successful. It may have been that the preparations were poor. It has been stated lately that success has been attained by the use of stock vaccines, but in my experience, which has been limited to the use of autogenous vaccines prepared in Jersey City by Dr. McDowell, they also seemed to be unsuccessful. I do not wish to be understood as in any way depreciating the value of experiments in this direction, but I am still waiting and hoping that the results reported will make it desirable for all of us to use these

remedial agents for the destruction of bacteria which enter into the diseases we have to treat.

DR. CASSELBERRY, Chicago: I have been particularly impressed with the favorable statement which has been given by one of the essayists, Dr. King, who refers to the pronounced favorable effects of tuberculin on laryngeal conditions in pulmonary tuberculosis, since we have not had up to this time any judgment or verdict in this respect based on so large an experience as he has had in this complication of tuberculosis. When the larynx is involved it becomes almost the dominant factor in the case, and our results up to this time have been discouragingly bad. Therefore, if — as we have hoped for the last few years with the trend of the verdicts with respect to tuberculosis — we have a remedy in tuberculin which will have in any considerable percentage of cases such effect as he has stated, we have made an enormous advance. I have been impressed with the statement that in those cases in which he got very pronounced reactions from a larger dose than was meant, the effect was good. This I have noticed many times in making the tuberculin test when it was given for the purpose of producing a general reaction; I have noticed that weeks and even months afterward there has been marked improvement in the larynx. I noticed this, but did not trust to my own observation, but gave the credit to other circumstances, — but the two go together: he has attributed it to tuberculin, and I have no doubt that he is correct. I have also had a limited experience with respect to the effects of the present-day minute doses in laryngeal cases, in which recourse was made to all other medical and surgical treatment. Elsewhere, I have reported 40% of arrested cases in laryngeal tuberculosis, some of them being those in which tuberculin in small doses had been given as an element of the treatment. Many of the men who see large numbers of pulmonary cases fail to examine the larynx. If these men would take note of the condition of the larynx and the effects on conditions there produced by tuberculin treatment, much good would be done to humanity in the direction of laryngo-pulmonary tuberculosis.

DR. DUNN, Asheville, N. C.: There are only one or two points in these very excellent papers which I wish to comment upon. First, I want to say that it is just such good, conservative papers as these which help. The tuberculin cause has been damaged more by optimists than by anything else. The effect of tuberculin in laryngeal tuberculosis has interested me for many years. I always examine the larynx, and I have been particularly struck with the improvement taking place in distinct laryngeal involvement. It is not so very striking in the advanced cases where there are marked destructive changes. As to the improvement following the reaction, it has been my custom to watch for reactions, and I have in many instances seen the beginning of improvement in the laryngeal reaction; it has happened so frequently that I am convinced it had some association with the reaction. As to the different forms of tuberculin, I have used a number of them; I used the old tuberculin constantly and exclusively for nearly ten years; for the last few years I have used the human bacillus culture, and recently I have used the bouillon filtrate of Denis, and I have used other methods in vogue at times. I have used the B. E. and the B. F. mostly of late, but the immediate results have been practically the same; I cannot see that I have gotten any better results from bacillus emulsion or from B. F. than from the old tuberculin. Not enough time has yet elapsed to form a positive opinion as to the use of tuberculin. I am very conservative as to its value; on the other hand, I do not think our attitude should be that of giving a person the choice of taking it or not as he pleases. When I give tuberculin to a patient I expect him to take it, just as I expect him to obey when I tell him to go to bed, and if I am convinced of its usefulness, that is my privilege. As to waiting until the improvement under hygiene and diet have been tried, that is not fair; if we are convinced that it has a value in making results more permanent, it is our duty to our patients to do that which gives them not only the best immediate results, but the best permanent chance. The time element is a very important one. I have known of a number of patients who took it for only a few months and then discontinued it and were put into a state of instability. That has been my impression.

Another thing: The greatest disadvantage in tuberculin is that the doctor puts his faith in his hypodermic syringe and does not pay enough attention to the life of the patient. We should never lose sight of the fact that it is a more or less important adjunct. Sometimes the patient puts more faith in what he gets from the hypodermic syringe than from what he does for himself. We should make them believe that what they do is of more importance than what we can do, and that the hypodermic is an aid, and nothing more.

DR. I. H. HANCE, Lakewood: A few months ago I read a short abstract of an article written by a Frenchman, — only a few lines, but in line of what has been said about the auto-inoculation, — to the effect that in treating pleuritic effusions he drew 2 ccm., and then reinoculated his patient. He reported four or six cases of value treated in that way. In view of this, I asked Dr. Trudeau if anything had been done at Saranac Lake with auto-inoculation with the serum. It occurred to me that if that were drawn off as horses' serum is drawn it could be successfully used on the patient, — the serum being drawn from the body. This is in line with what Dr. Cohen said — leaving the serum under the blister for reabsorption and auto-inoculation that way.

H. S. BIRKETT, and J. C. MEAKINS, of Montreal, read a paper on

THE VALUE OF VACCINE TREATMENT OF CHRONIC INFLAMMATORY DISEASES OF THE ACCESSORY SINUSES OF THE NOSE.

DISCUSSION.

F. C. COBB, M.D., Boston: The question is a most complicated one and the results thus far obtained are both discouraging and encouraging. In a series of twelve cases at the Massachusetts General Hospital, all of the patients treated with vaccine made from a bacillus found in all cases, a general improvement was shown, and yet no absolute cure can be reported.

DR. H. C. REIK, Baltimore: I think that if I had had the opportunity of drawing my conclusions after having heard these papers, I should not make them different. I regret that more was not said regarding the use of vaccines in relation to the nose and ears. The fact that the climatologists seem to have gotten away with the discussion may perhaps be explained by the well-known timidity of the rhinologists and the well-recognised modesty of the otologists. One point was brought out by Dr. Birkett, and confirmed by the negative reports of results found by both Dr. Cobb and Dr. Coakley, that one positive result is worth many negative findings. Then in his conclusion that treatment by vaccines will sterilize the accessory sinuses of the nose, — and there seems to be evidence to back up the statement, — he has given us something very important to think about. None of the essayists spoke of many positive results having been obtained in the treatment of the nose, — and if that be true, that we can bring about a state of sterility of the secretions, much can be

accomplished by the treatment, even though some remains. None of us are afraid of sterile secretions from the nose. We have good reason to be afraid of infectious secretions from the nose.

DR. R. G. CURTIN, of Philadelphia, read a paper entitled

A BRIEF STUDY OF THE CLIMATOLOGY OF CANCER.

DR. THOMAS DARLINGTON, New York, N. Y.: I think there is very little value in the statistics which are collected to-day. Some time ago, in investigating cases of meningitis and the statistics as reported in the city of New York, three out of every five cases were found not to be cerebrospinal meningitis, but two were meningitis, two were pneumonia and one was enteritis. Now if our statistics are of the same character, we cannot depend upon them, and I feel that our cancer statistics are in the same nature. The one trouble with statistics of this character is that a great many people feel that cancer, like tuberculosis, is hereditary, and if a person dies with any symptoms of pneumonia or Bright's disease, that is usually placed on the death certificate and the cancer not mentioned because of its bearing on the future life of the children. That is a very common affair. I feel that we need some other method of collecting vital statistics, possibly that every case should be visited by an inspector and the certificate granted by him, instead of the physician. So far as people in the cities being subject to cancer, there is no doubt that where people are gregarious they cannot expect the immunity of a disease that follows the forest. I feel that our statistics are so faulty that we really know nothing about it, and I have made many investigations along that line. I only wish that we could do something to secure better registration in the various cities and states.

DR. C. L. MINOR, of Asheville: Speaking for the South and those sections where the negro greatly predominates, I am satisfied that proper vital statistics are utterly impossible. As to whether there are many cancers among the negroes or not remains to be proven, but I am sure that if any there may be, only a minute fraction would be reported. A large majority of all negroes, and especially of country negroes, have no doctor, or such doctors as would never report. But leaving the negro aside, statistics of disease in the rural whites, living, as they often do, miles from the nearest doctor, and he miles from the registering office, are out of the question. In the thickly settled country, with many officials and people trained to carry out registry law, it is different. But for the portions of our country which are purely agricultural and where anything but villages are rare, we need not anticipate sta'istics which would be of any value.

DR. FREMONT-SMITH, of Washington, D. C., read a paper on

INFECTIVE ENDOCARDITIS IN THE YOUNG.

DR. HENRY L. ELSNER, of Syracuse, read a paper on

THE CONTROL AND TREATMENT OF HYPERTENSION AND ARTERIOSCLEROSIS.

He stated that cardiovascular, more particularly arterial, changes furnish the fundamental morbid processes in the largest number of deaths after the fortieth year. There is a physiologic hyperplasia invading the intima during early life. We must consider the separate artery as an organ whose task is multiple, and the performance of its daily undisturbed work is attended even during the earliest years of life with a compensatory deposit for the preservation of these organs and the continuity of the circulation. As soon as this physiologic hyperplastic change of the intima, because of age, overwork, strain, toxemia or any other cause, is forced into a stage of hypertrophy, we have the beginning of arteriosclerosis. Hypertension upon which we fail to make a favorable impression by rational treatment is already associated with changes in kidney, heart or within the splanchnic area.

Hypertension will often lead to a strong suspicion of renal invasion. Dr. Elsner took up the influence of tobacco and quoted Sir Lauder Brunton's experiments in which a rise of blood pressure is noted after the use of nicotine. This is greater than from any known drug except suprarenal extract. This is due chiefly to contraction of the arterioles. Coffee also raises the pressure, and Dr. Elsner advocated the "caffeine-free" coffee. The dietetic management of these patients is most important. Many patients with angina pectoris have promptly lost their lives because of a single dietetic indiscretion. Dr. Elsner advocated the use of the Zander movements and believes that the use of the apparatus has not been properly appreciated by the profession in the treatment of hypertension. High-frequency currents were also highly recommended. The preparations of iodine were discussed, especially the newer ones, including sajodin, tiodin and eustenin. The alcoholic solution of nitroglycerin was advised and sodium and amyl nitrite. Dr. Elsner has given fifteen drops of nitroglycerin solution in desperate cases with benefit.

DISCUSSION.

DR. CURTIN said that in his investigation of angina pectoris three years ago he studied its relation to the use of tobacco. He then reported 60 fatal cases; of these he personally knew 8 men who did not use tobacco and in addition there were 15 women who presumably did not smoke, making 23 of the total of 60 persons, or about one third in whom tobacco could not be ascribed as the cause. One was noted as a great user of tobacco, and that is the only one in which my notes mentioned tobacco at all. Men who smoke and are leading active lives die of angina pectoris, and females who live similar lives die of it, too, and we may suppose that they do not smoke. In Japan almost the whole population smokes, — the boys begin at nine and the girls at ten, and yet angina pectoris is said to be not a very common disease in Japan. "I should say that, as far as my observation goes, tobacco is not a strong factor in the cause of the disease, but when the disease appears it may be aggravated very much by tobacco, or any other mild cause, particularly in regard to taking of food and drink. Anything that distends the stomach, and particularly food, may bring on an attack of angina pectoris. A bishop told me that when he got behind a horse and that horse began to ascend a hill he got an attack of angina pectoris; and there was another person in Philadelphia who said that when he got to a certain point where he used to run to catch a car, and saw the car stop still, he got an attack, showing that the imagination has a great deal to do with bringing on a paroxysm."

DR. ELSNER said that Hag, of Bremen, several years ago brought to the notice of the German profession a caffeine-free coffee, from which all but about 10% of the caffeine had been eliminated. Dr. Elsner had considerable experience with this caffeine-freed coffee, and is very positive that it is not followed by the baneful effects on the heart following the use of ordinary coffee, and it is a coffee which may be given without fear to those who cannot take coffee at night without being kept awake. It is not a substitute for coffee, but a true coffee. No difference is apparent in the bean and there

is no difference in the taste when properly prepared. This coffee may be used by those who do not bear ordinary coffee well, those who have arteriosclerosis and irritable hearts.

Dr. Judson Daland and Dr. W. D. Robinson, of Philadelphia, read a paper on

ANGINA PECTORIS AND TOBACCO.

They stated that smoking by a novice causes a rise of blood pressure of 10–20 mm. Hg.; that in a moderate smoker the rise is about 10 mm. There is no sudden fall in pressure, but an increase in pulse-rate. Moderate smoking by one accustomed to its use shows no change in blood pressure or pulse-rate. These data were quoted from Emerson Lee. Experiments on rabbits by Adler were given. Osler, Krehl and Huchard were quoted as believing that angina pectoris may be induced by tobacco. Four cases were cited illustrating the relationship of tobacco to angina pectoris. Tobacco in excess induced the attacks, and its withdrawal diminished their number. Over-eating and the use of alcohol was a cause associated with tobacco, the latter being the chief cause. The result of exertion was noted. The conclusion was that long-continued excess of tobacco by smoking a large number of cigars daily produces that syndrome known as angina pectoris by causing degeneration or chronic inflammation of the terminal fibers of the vagus in the heart and a similar change in the middle coat of arteries. It is probable that other widespread and important pathologic changes are caused by chronic tobacco poisoning, many of which act as contributing factors in the production of angina pectoris.

DISCUSSION OF PAPERS OF DR. ELSNER AND DR. FREMONT-SMITH.

Dr. C. L. Minor, of Asheville, N. C.: Unlike some of my friends who have discussed the question, I am not a smoker, so that I am free of bias in the matter. Doubtless to the smoker these papers would recall the remark of the lady who said that, after all, in this world everything that was enjoyable was either expensive, unhealthy or wicked. What I wish to note in Dr. Elsner's paper is what he said of Dr. Rush's observations more than a century ago. We doctors have an opportunity to notice how terribly the nerve tension of the American people is increasing, and any one who will go to a picture gallery and compare the faces of the Americans of 1840, before railroads were everywhere, before the telegraph was known, or when the telephone did not keep our nerves on the *qui vive;* when the automobile and the airship were not dreamed of, and when we lived more slowly and more sanely, with those of the present era — when these and many other things are pushing us faster and faster forward — will notice the wonderful difference in the faces produced by these things and can well believe that there must also be a change in our bodies. There is a calmness and a quietness in the portraits of our grandparents, and, if we are not too young, of our parents, which we do not often see in these days when life is lived at lightning speed and calmness and meditation are strange.

I believe, therefore, that our profession can do much by warning their patients against this overtension and overworry and teaching them that such conditions of mind are bound to react on their body.

Dr. Hall, of Denver, Colo.: The case I wish to speak of is so much more impressive to me than any case of clinical reports would be. I saw some six years ago a physician then thirty-four years of age who had a suddenly developed attack of asthma following hypertension. He had been treated in Chicago, Liverpool and London for his asthma and finally returned to Colorado. He came to Colorado hoping for relief, but the climate gave him no help. I suggested that he try a hypodermic of adrenalin solution. He did not want to try it, but finally did. It gave him the first ten minutes of absolute relief from asthma that he had had for years. Since that time he has used 200 oz. in the course of 1:1,000 solution of adrenalin. The man would never go down town without two hypodermics in his pocket for fear of one breaking. He has at times taken sixty hypodermics in twenty-four hours. I had occasion to examine him a month ago and went over his arteries. His arteries are soft, his blood-tension was 132, entirely within the normal limits. I asked one or two other clinics to examine his arteries and they found them absolutely normal. I asked Dr. Stevens, who is one of our noted clinicians, to examine his arteries to see if there are any indications of the use of adrenalin. There was no indication of it. He has recovered from his asthma and gained 77½ lb. over his lowest weight, weighs 190 lb. now, and is ready for his practice of medicine.

I wish to say very briefly that I certainly agree with the doctor, in examining the heart, that tobacco has an influence upon it. I think I can tell the time of the year when May comes because of the number of teachers who come in all tired out. In the same way I can tell when a financial panic is pending by the number of men who are in heavy business who get anxious about the situation and smoke, — the kind of men who smoke fifteen or twenty cigars in a day and then wonder why the heart is affected. One man whom I knew lost two million dollars, and his heart dilated until it was two inches to the left of the left nipple. By cutting off his tobacco, and the closing up of the panic, and his final resignation to the loss he had suffered, and a treatment at Carlsbad, he was finally restored. I think Osler says that angina pectoris is common among doctors; I have not yet known any doctor to have it over the loss of two million dollars in the panic.

Dr. J. M. Anders, of Philadelphia, Pa.: Dr. F. Fremont-Smith included under the title of infective endocarditis only ulcerative endocarditis. On the other hand, certain writers are in the habit of including under the same caption both forms of acute endocarditis. It seems to me that we are in need of a classification that should be universally adopted. During childhood ulcerative endocarditis is more often associated with acute articular rheumatism than any of the other infective diseases of early life. There is a surgical group of cases due to bone diseases, to skin infections and particularly osteomyelitis, which group is not uncommon in young subjects, and I am sure frequently overlooked. Dr. Smith's cases belong to that group known as "recurrent ulcerative endocarditis," perhaps the least difficult of all forms to diagnosticate. Again, in a case of chronic endocarditis, the development of a septic condition, even in the absence of a septic focus elsewhere in the body, justifies the clinician in making a clinical diagnosis of ulcerative endocarditis. The cases in which the cardiac signs are unusually prominent are most readily recognized, but in my experience these cardiac signs are most indefinite as a rule, and, while we hear much about the change in the character of the murmurs due to chronic endocarditis, I have been struck by the fact that more commonly than a noticeable change in the character of the murmur there is present a moderate degree of secondary dilatation of the left ventricle. I think this is a point that is probably often overlooked. I was glad to hear Dr. Elsner lay down that important clinical truth that hypertension is not the sole cause of angina pectoris, but, on the other hand, cases of hypertension may manifest this

dangerous condition. He spoke of the case of hypertension that could not be readily relieved by treatment, and that cases of that sort were to be regarded as instances of hypertension due to arteriosclerosis. This is true provided that the treatment employed is entirely appropriate, but as he so well said, unless one gives massive doses of nitroglycerine or other arterial relaxants, in many of these cases the arterial spasm is not relieved and then we are apt to confuse an arterial spasm with high tension due to arterial changes. Of this I have seen a number of illustrations.

A word with reference to the influence of tobacco as a cause of angina pectoris. I quite agree that it may be, although rarely, the principal factor in bringing about this grave condition. But without exception in my experience the cases in which it has seemed to stand in an etiologic relation, other causative agencies have been at work and easily recognizable. For example, a man suffering from aortic incompetency developed angina pectoris after smoking strong cigars, and quite recently a case of arteriosclerosis of moderate degree associated with marked arterial spasm fell under my observation, and in that case the use of strong cigars seemed to excite an attack of angina pectoris; at all events, treatment by rest, removal of the weed and by small doses of nitroglycerine led to a practical cure. We all know, as has been said by Dr. Elsner, that tobacco rapidly raises the arterial tension. It does so by inducing spasm of the arteries, and as the result of my observation for many years I believe that this is the most important influence of tobacco. I am aware that certain writers contend that nicotine produces widespread degeneration of the aorta in animals and that it causes arteriosclerosis of the coronaries. I have never seen a case of coronary disease that I could attribute solely to the use of tobacco. I have, however, as Dr. Curtin has so well said, seen many cases of rather marked arrythmia with accelerated action of the heart due to smoking, but this is an entirely different condition from true coronary disease, because the removal of the tobacco in these cases is invariably followed by a normal pulse-rate and the disappearance of the arrhythmia.

DR. H. L. ELSNER, of Syracuse, N. Y.: I think it is particularly those cases in which there is an hereditary tendency that are influenced by tobacco. It is pretty difficult to say that tobacco is provocative of angina, but we do know that many of these cases get better when we drop the tobacco.

In regard to the x-ray, I am glad to see this demonstration which Dr. Daland made. I think we use the x-ray too little.

With regard to the frequency of angina pectoris, women have it more rarely than men. For instance, in our statistics from Central New York, in the 44 cases of angina that were included, there were only three or four women. They bear angina pectoris long because they can relax better than men; they have less weighty responsibilities; they know how to rest; that is the reason why they have it less and live longer.

Now with regard to the good bishop's experience, there is a large psychic element. I know of a miller who never had an attack in his mill, but the moment he walked outside the mill against the wind he had an attack. I know a physician who recently consulted me, and said: "I may go to a medical meeting and walk home with my colleagues and I never have it, but if I go alone I have the pang." Angina may exist without the fear of death.

With regard to the aortic second accentuation there are a very few cases of hypertension which have existed for a very long period of time in which, as Sir Lauder Brunton says, the door is not slammed. This is likely to be the case when the aortic cusps are closed after the heart has made the attempt to overcome the obstruction in the periphery.

DR. JUDSON DALAND, of Philadelphia, Pa.: As angina pectoris is merely a syndrome; it naturally has many causes, and the object of this paper is to point out that Case 1 clinically seems to demonstrate that tobacco was the chief cause; and that in Cases 2, 3 and 4, all relatives, presented multiple causes but that tobacco was the chief cause, Cases 2, 3 and 4 all being brothers, and the sister, fifty-two years of age, was without and did not use tobacco.

I desire also to make clear the fact that tobacco was perfectly able to produce neuralgic effects. That is known to all of us, I am sure. I also agree with Dr. Elsner regarding the therapeutic importance of sleep in hypertension and arteriosclerosis; the inability of possible control of hypertension by any of the ordinary methods except those directed to the removal of the poison by measures such as the hot-air bath, etc. In these toxic cases nitroglycerine and the nitrites have not in my own hands been successful in attempting to lower high blood pressure.

At the last business meeting the following officers were elected for the ensuing year: President, Dr. John Winters Brannan, of New York; vice presidents, Dr. Will Howard Swan, of Colorado Springs, and Dr. John H. Lowman, of Cleveland; secretary and treasurer, Dr. Guy Hinsdale, of Hot Springs, Va.; representative on the executive committee of the ninth Congress of American Physicians and Surgeons, Dr. Roland G. Curtin, of Philadelphia.

It was decided to hold the next annual meeting in June, 1911, at Montreal, Canada.

Book Review.

Ionic Surgery in the Treatment of Cancer. With a Chapter on Ionization in Surgical Tuberculosis and in Hemorrhoids. By G. BETTON MASSEY, M.D., Attending Surgeon to the American Oncologic Hospital; author, "Conservative Gynecology and Electro-Therapeutics"; Fellow and former President of the Electro-Therapeutic Association; Member of the American Medical Association, etc. New York: The A. L. Chatterton Company. 1910.

Here is a book of two hundred and forty-three pages, written in all earnestness and simplicity by an author who remarks in the fifth line of his preface that his method "was first presented to the medical world in a paper read before the Philadelphia County Medical Society Jan. 9, 1895." Ionic surgery is a method of electrolysis. It has its limitations and its advantages; it appears to cure small superficial malignant growths; it is little effective in the case of extensive, deep-seated disease. Those surgeons and patients who dread the knife, who cannot afford radium and are skeptical of the x-rays may turn for relief to the promises of ionic surgery.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, NOVEMBER 17, 1910

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 Tremont Street, Boston, Mass.

THE SUPERHEATED AMERICAN HOUSE.

The season of superheated houses has again arrived. As soon as the bracing crispness of the autumn air begins to exert its normal stimulus on the heat-producing power of the human body, the average American householder lights his furnace fire, raises the thermometer in his rooms to 76° or more, sits in those rooms all the evening, with the additional heat of a fiery kerosene lamp baking on his head, and then wonders why he shivers when he goes outdoors to his work in the morning and why in a few days he develops a typical "fall cold." Not only are most private houses made thus uninhabitable, but nearly all public buildings and institutions are similarly superheated by steam or hot air.

Nor is the temperature the whole or even a major part of this evil. Thanks to the heating devices which American ingenuity has invented, the atmosphere in such buildings is usually about twice as dry as that in the desert of Sahara. And this is literally true, for the mean humidity in the desert is 30, and that in a steam- or furnace-heated house often runs as low as 16. Any one who has had experience with potted plants indoors knows the rapidity with which water evaporates from their saucers. With like avidity the parched air of our houses absorbs moisture from our skins and from the mucous membrane of our respiratory tract, with consequent drying and congestion, which prepare the way for the entrance of infection.

The human organism is a cunning machine, with possibility of adaptation to a wide range of conditions, but it will not stand such treatment. It does its best for a time, but sooner or later comes a series of "colds" and the establishment of the chronic American nasopharyngeal catarrh. Superheated houses and dry air are responsible for these ailments far more than the much-maligned east wind, which is really one of the mitigating factors that make our climate endurable, because it brings moisture "from the caves of the misty Atlantic."

In noteworthy contrast to our methods is the English fashion of doing. In England the furnace is almost unknown. Houses are heated by open fires, or occasionally by stoves, and seldom heated above 60° at that. The English air is so much moister than ours — thanks to the Gulf Stream which we furnish — that it oozes perennially, with the result that verdure is greener and more luxuriant, flowers brighter and complexions far clearer and ruddier than in our country. The people are not afraid of cool moist air, and they take it into their houses without robbing it of its humidity by steam-heat.

Let this diatribe not be interpreted as inexorable anathema or unqualified praise. Doubtless there should be a desirable middle course between the American and the English custom. The English habit perhaps predisposes to the rheumatoid diseases; ours certainly leads to colds, catarrh and bronchitis. The heat of our houses upsets our temperature-regulating mechanism so that it fails to work when we go out; and the dryness robs our superficial tissues of their juices. The cells of man's body are aquatic by heredity, and thrive better in contact with normal saline than in any other medium. To treat them as we often do is to deprive them of their birthright, and they are avenged upon us accordingly. It were a genuine advance in preventive medicine to provide for the cooling and humidifying of our houses as well as for their ventilation. The superheated American house is a medical barbarism and an anachronism in enlightened progress.

PULMONARY HEMORRHAGE AT HIGH ALTITUDE.

In a recent reprint from the reports of the United States Public Health and Marine-Hospital Service, Dr. F. C. Smith presents a statistical study of "pulmonary hemorrhage in the tuberculous at high altitude." This study is based on a series of 56 deaths from such hemorrhage during the past ten years at the Marine-Hospital sanatorium at Fort Stanton, N. Mex., which is situated at a height of 6,200 feet above the sea level. Tabulation and examination of these cases seem

to indicate that pulmonary hemorrhage directly causes about 10% of the total mortality from phthisis; that such death is not proportionately more common in one decade of life than in another; that syphilis and chronic alcoholism increase slightly the liability to fatal hemorrhage, but probably only in proportion to the usual lesser vitality of such individuals; that massive hemorrhages are often and small hemorrhages seldom suddenly fatal; that recurrence of hemorrhage rarely or never occurs after bronchopneumonia develops; that fatal hemorrhage is seldom due to exertion, but commonly supervenes during sleep, in which case death is due more often to suffocation than to loss of blood.

Most commonly associated with such cases was organic cardiac disease, of one sort or another, which Dr. Smith regards as a frequent cause of the fatal issue, though not as a predisposing cause of hemorrhage. *A priori*, high altitudes should increase such deaths from cardiac failure during hemorrhage, since by diminishing blood-pressure they still further embarrass already imperfect heart-action. Actually, however, they do not seem to lead to more frequent pulmonary hemorrhage, since, in Dr. Smith's cases, hemorrhage was not more common immediately after arrival from sea-level.

Chronic types of phthisis are most liable to fatal hemorrhage; and hence negroes, in whom the disease usually runs a rapid course, showed a lower mortality from hemorrhage than whites.

Dr. Smith's conclusions seem in the main to bear out the general supposition that high altitudes are on the whole favorable for the care of hemorrhagic cases of pulmonary tuberculosis. When they are not so, it is because of their untoward effect on a pre-existent cardiac lesion. In cases with such condition, physicians should be particularly careful in recommending a high altitude, on account of its depressing action on the heart.

AN ISOLATION PAVILION AT AIX-LES-BAINS.

MR. J. PIERPONT MORGAN has given $40,000 for an isolation pavilion in connection with the Municipal Hospital at Aix-les-Bains, France, and Dr. Paul Guyenot, head of the Zander Institute in that place, and one of the best-known authorities in Europe on physiotherapy, is now in this country, on Mr. Morgan's invitation, for the purpose of making a study of hospital construction and methods here. The plans for the pavilion have been drawn by T. Markoe Robertson, a grandson of the eminent New York surgeon, the late Dr. Thomas M. Markoe, who was the architect of the isolation wards on the roof of the New York Lying-In Hospital, whose admirably equipped new building was rendered possible through Mr. Morgan's generosity.

Incidentally, Dr. Guyenot has been requested by the French government to make an official report on the management of tuberculosis in America. In speaking of his mission here he recently said: "Mr. Morgan has been coming to Aix-les-Bains for treatment for fifteen years, and has been very generous to the little community of 8,000 people who live there. Ten years ago he gave $40,000 toward the fund for the new Municipal Hospital, and two years ago he gave an additional $8,000 for the equipment of a department for administering x-ray and electrical treatment. Now he is paying the total cost of the projected isolation pavilion, which is to accommodate twenty-two persons, and will be modeled after the isolation wards at the Lying-In Hospital here. It is not intended to be used as a sanitarium, and will be entirely free. This country is very much in advance of Europe in its measures to prevent the spread of tuberculosis. The hospitals I have seen in New York impressed me as exceedingly progressive and thorough in interior arrangements. Of course, in Europe there are not as a rule such large sums of money available for such institutions, though the Effendorf Hospital in Hamburg, which was erected regardless of cost, is a splendid monument externally. The interior, however, is not in accordance with the most approved modern ideas, and cannot be compared with either the New York Lying-In Hospital or the Rockefeller Institute Hospital, which I consider the two finest institutions of their kind in the world. The latter hospital is simply magnificent in its arrangements for studying special diseases and observing different methods of treatment. The arrangement of the isolation building there is remarkable. Physicians and nurses going to one room to attend a patient pass through corridors enclosed in glass, separating it from other rooms, and before leaving the building they take a bath and change their clothing, so that there is no risk of infection by the carrying of germs."

MEDICAL NOTES.

A SPECIAL CLINIC. — The New York and New England Association of Railway Surgeons were given a special clinic at the New York Post-Graduate Medical School and Hospital, Nov. 4, 1910.

Subsidence of Cholera in Italy. — During the week ending Nov. 12, only 13 new cases and 5 deaths of Asiatic cholera were reported from Italy. The subsidence of the epidemic there seems now to be well marked.

Typhoid Fever at Annapolis. — Ten cases of typhoid fever are reported to have developed recently among naval cadets at Annapolis, Md. No source for the epidemic has been as yet determined.

Poliomyelitis at Cornell. — Report from Ithaca, N. Y., states that two cases of acute poliomyelitis, the first to occur in that city this year, have recently developed among the students at Cornell University.

Award of the Davy Medal. — Report from England states that the Davy Medal has been awarded this year by the Royal Society of London to Theodore William Richards, Ph.D., Sc.D., professor of chemistry in Harvard College, for his researches on the determination of atomic weights.

Prevention of Water Pollution by Trains. — It is reported from Albany, N. Y., that, as a measure of protection to the water supply of New York City, the State Health Commission has ordered the closure of all washrooms on railroad trains during their passage through the limits of the Croton watershed.

United States Government Food Charts. — The United States Department of Agriculture has recently issued a series of food charts presenting in graphic form the composition and caloric value of various foodstuffs, with suggestions for the proper arrangement of dietaries. These charts, for use in schools, may be obtained from the Superintendent of Documents, in the government printing office, at a cost of $1 a set.

Two Living Centenarians. — Mr. Ransom Young, of Drums, in the township of Butler, near Hazleton, Pa., is said to have been born on Nov. 8, 1810. He is now very feeble, but on the recent anniversary of his birthday was taken to the polls and cast his vote in the state election.

Mr. Samuel Putnam, of New Salem, Mass., who is locally reputed to have been born on Nov. 9, 1806, is said to be in excellent physical health, though now failing mentally. He has never used alcohol or tobacco, and has always been an advocate of total abstinence and of universal peace. He has one surviving son, one grandson, and three great-grandchildren.

Association for Prevention of Infant Mortality. — The annual convention of the American Association for the Study and Prevention of Infant Mortality, which was held on Nov. 9, 10 and 11 at Baltimore, Md., was attended by representative physicians, sanitarians, sociologists and political economists from many states. At the opening session, addresses on "The Duty of a Nation to Its Potential Citizens" were made by Dr. William H. Welch, of Johns Hopkins Medical School; by Dr. Abraham Jacobi, of New York; by M. Jusserand, the French ambassador; and by Prof. Irving Fisher, of Yale College, president of the committee of one hundred on national health.

Copies of the "Medical Libraries" as a Gift. — Dr. C. D. Spivak, Denver, Colo., formerly editor of *Medical Libraries*, a bi-monthly publication devoted to the interests of medical librarians, which closed its somewhat irregular and spasmodic career in 1902, offers to send to all medical librarians and to all who are interested in medical journalism complete sets of Vols. 2, 3 and 4, and incomplete sets of Vols. 1 and 5, of that periodical for the asking. "All the sad editor desires in return is that these his dear departed ones be reverently laid out, decently shrouded, adequately coffined, properly epitaphed, securely inhumed and unostentatiously gathered unto their fathers."

Damages for Death under Chloroform. — On Nov. 11 a jury of the Supreme Court in New York City awarded a verdict for $3,000 damages in a suit brought against a physician by the mother of a patient who died under chloroform anesthesia. The doctor is alleged to have administered the drug to abate the boy's resistance to the application of leeches to an injured knee. Such use of a general anesthetic would, of course, be entirely unjustifiable. Whatever the facts in this case, the known dangers of chloroform are sufficient to warrant the cautious in the utmost reluctance from its exhibition under any circumstances.

Medical Addresses to School Superintendents. — At the opening session of the eighty-seventh meeting of the New England Association of School Superintendents, held in Boston last week, addresses were made by a number of physicians on problems connected with

the health of school children. Dr. Eugene A. Darling, of Cambridge, Mass., assistant professor of physiology in Harvard College, discussed the desirability and methods of anti-tuberculosis teaching in the public schools; Dr. Jay Perkins, of Providence, R. I., described the proper instruction of the open-air school; and Dr. Cleaveland Floyd, of Boston, emphasized the value of such schools and the improvement in mental as well as in physical vigor of pupils sent to them. Dr. H. Lincoln Chase, of Brookline, Mass.; Dr. Lewis H. Palmer, of South Framingham, Mass.; and Dr. Gardner T. Swarts, secretary of the Rhode Island State Board of Health, spoke on the topic of "The Serious Consequences of Ignorance of Sexual Hygiene." It was voted to appoint a committee to investigate the methods of teaching this branch of hygiene in the public schools.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.— For the week ending at noon, Nov. 8, 1910, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 50, scarlatina 26, typhoid fever 29, measles 8, smallpox 0, tuberculosis 54.

The death-rate of the reported deaths for the week ending Nov. 8, 1910, was 13.90.

BOSTON MORTALITY STATISTICS.—The total number of deaths reported to the Board of Health for the week ending Saturday, noon, Nov. 5, 1910, was 193, against 215 the corresponding week of last year, showing a decrease of 22 deaths, and making the death-rate for the week, 14.94. Of this number 96 were males and 97 were females; 188 were white and 5 colored; 111 were born in the United States, 78 in foreign countries and 4 unknown; 41 were of American parentage, 129 of foreign parentage and 23 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 39 cases and 1 death; scarlatina, 38 cases and 1 death; typhoid fever, 28 cases and 8 deaths; measles, 8 cases and 1 death; tuberculosis, 60 cases and 17 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 20, whooping cough 0, heart disease 33, bronchitis 5. There were 12 deaths from violent causes. The number of children who died under one year was 32; the number under five years, 43. The number of persons who died over sixty years of age was 59. The deaths in public institutions were 76. Cerebrospinal meningitis, 2 cases and 1 death. Anterior poliomyelitis, 2 cases.

Of the above infectious diseases the following were non-residents: Consumption, 1 case and 1 death. Scarlet fever, 5 cases. Typhoid fever, 3 cases.

Deducting deaths of non-residents, the total is 176 and the death-rate is then 13.62.

NOMINATION FOR MEDICAL EXAMINER. — Dr. Henry J. Walcott, of Concord, Mass., was last week nominated by the governor as medical examiner for the sixth Middlesex district.

LEGACY TO THE NEW ENGLAND HOSPITAL. — The will of the late Lucretia Gore French, of Boston, filed in probate last week, contains a bequest of $2,000 to the New England Hospital for Women and Children.

SEIZURE OF COCAINE BY THE POLICE. — At a raid made last week by the police on a den in Roxbury, $500 worth of cocaine was seized, with a number of pipes and other utensils employed by habitués, of whom seven were arrested on the premises. The prisoners will be arraigned on the charge of keeping cocaine for illegal sale and of unlawfully disposing of the drug. It is stated that in the district where the seizure was made there are numerous similar resorts which will probably be raided within a short time. It is both surprising and discouraging to find how difficult is the eradication of so repulsive a vice from our community.

FAIRS FOR CHARITABLE INSTITUTIONS. — During the past week several sales or fairs for the benefit of charitable institutions in or near Boston, which we announced in the latest issue of the JOURNAL, were successfully held, and substantial sums of money were made for the Cullis Consumptives' Home, Dorchester; for St. Monica's Home, Roxbury; for the Somerville (Mass.) Hospital, and for the Day Nursery, Brookline, Mass. The work of these institutions was also inspected by patrons of the fairs. On Tuesday of this week, Nov. 15, was also held by the Board of Directors of the Blind Babies' Aid Society a Thanksgiving sale for the benefit of the Boston Nursery for Blind Babies, now installed in its new building in Jamaica Plain. This building is free from debt, but the institution is dependent for its maintenance on voluntary private contributions.

MILK AND PURE FOOD CONVICTIONS. — In the Boston Municipal Court last week, ten local milk dealers were fined sums varying from $10 to $60 each for having in their possession for sale skimmed milk or milk not up to the minimum

standard required. Before the same court another dealer was fined $15 for offering for sale oleomargarine without displaying a notice to that effect; and still another was fined the same amount for selling molasses vinegar as cider vinegar.

In the Malden (Mass.) District Court, a Maine contractor was accused of shipping for sale milk below the required standard. In defense his counsel alleged that the milk as shipped was not intended for sale until after being mixed with other and stronger milk. This plea was not allowed by the court, and the defendant was fined $15, from which he appealed.

Meeting of the Improvement Society. — A meeting of the Boston Society for Medical Improvement was held in Sprague Hall, Boston Medical Library, on Nov. 14. Dr. M. G. Seelig, of St. Louis, read a paper on "The Doctrine of Vitalism in Medicine," which will be published in a later issue of the Journal. This paper was discussed by Dr. James J. Putnam. Memorial addresses on the life, work and character of the late Dr. Herbert Leslie Burrell were then made by Dr. E. H. Bradford, Dr. G. H. Monks, Dr. F. S. Watson, Dr. J. B. Blake, Dr. M. H. Richardson and Dr. Paul Thorndike. Dr. Monks showed some particularly interesting photographs of the hospital ship *Bay State*, which Dr. Burrell equipped and commanded during the war between the United States and Spain in 1898, and with which he rendered valuable and efficient service not only to the troops cared for in Cuba, but to the cause and reputation of American military and naval surgery.

Typhoid Fever at Austin Farm. — There has recently been a small epidemic of typhoid fever among attendants at the Insane Hospital at Austin Farm. Fourteen cases have occurred in nurses and employees, of whom eight are now at the Boston City Hospital. There has been none among the 840 inmates of the institution. All the cases are mild and there have been no deaths. No new cases have been reported within the past ten days, and it is believed that the spread of the disease is now under control. The original source of the infection has not yet been discovered, and in the absence of evidence pointing to the food or water supply, it is believed that the epidemic may have had origin in a typhoid carrier recently come to the hospital. Investigations are in progress to determine if possible the identity of this suspected carrier. Such an episode reemphasizes the desirability of protecting the attendants of an institution, where opportunity is rife for spread of infection from such transient source, by means of antityphoid inoculation.

The Cost of Pure Milk. — On Nov. 10 and 11 was held in Boston a conference between the mayors and heads of departments of many of the cities of New England. This conference, which was called to promote uniformity of purpose and co-operation of method in the prosecution of various civic improvements in the several municipalities, was addressed on the subject of "The City's Inspection of its Milk Supply" by Prof. W. T. Sedgwick, of the Massachusetts Institute of Technology, who pointed out that adequate enforcement of laws for insuring the safety and cleanliness of milk is bound to raise the price of milk for the consumer. In view of the importance and high food value of milk, however, he believed such increase of cost to be worth paying. Dr. Thomas E. Maloney, of the Fall River (Mass.) Board of Health, described the system of milk-supply in his city, and declared that within a few years the number of tuberculous cattle in the vicinity were reduced from 37½ to 4%. Addresses on the same topic were made also by Dr. Durgin, of the Boston Board of Health, and by Mr. Jordan, of the city inspection bureau.

NEW YORK.

Increase in Minimum Rates for Medical Attendance. — At a recent meeting of the Suffolk County (Long Island) Medical Society, it was decided, in view of the increased cost of living, to advance the minimum rates for medical attendance. In some parts of the schedule of charges the increase is 25% and in others, 50%.

Yellow Fever One Hundred Years Ago. — The centennial of the founding of St. James' Protestant Episcopal Church, on Madison Avenue, at the corner of Seventy-first Street, which was celebrated on Nov. 13, brings to mind the great yellow fever epidemic of a hundred years ago. In consequence of the prevalence of the disease, many residents of the city were led to build country homes on the shores of the East and Hudson rivers, and as a considerable number of them were parishioners of Trinity Church, the latter gave substantial aid to the building and endowment of two rural churches, St. James' on the East Side, and St. Michael's on the West.

Decline in Birth-Rate. — In a recent report F. D. Beagle, director of the Division of Vital Statistics of the State Department of Health,

states that while, with the constant decrease in the death-rate, it would be natural to expect an increasing birth-rate, it appears that the slight increase from year to year shown by the returns filed in New York state is due to the improvement in the registration, as undoubtedly there is a tendency to a decline in the birth-rate. During the first six months of the present year there was over 10% increase in the registration of births over the corresponding period of 1909. Thirty-seven cities in the state show an increase, and twelve report fewer births than last year. The registration in the latter is at present being investigated by representatives of the department. It is most gratifying to be able to say, he remarks in conclusion, that at the present time there is the most complete registration of births in the state since the establishment of the State Department of Health in 1880.

ENLARGEMENT OF MONTEFIORE HOME. — At the annual meeting of the board of trustees of the Montefiore Home and Hospital for Chronic Invalids, held on Nov. 6, it was announced by the president, Jacob H. Schiff, that $850,000 had already been subscribed for the new buildings which it is purposed to erect for the institution. As the present property of the home, at Broadway and 138th Street, has been sold for $525,000, this leaves but $125,000 to make up the $1,500,000 which it is estimated will be needed for land, erection and equipment at the new location, and the required amount, it is believed, will be raised at an early date. Four blocks, comprising an area equivalent to 162 city lots, have been purchased in the Borough of the Bronx, and, in view of the benefit to the community conferred by the Montefiore Home in the past, the municipal authorities have consented to the closing of the streets between two of the blocks. The new buildings will accommodate some six hundred patients, and will probably be completed within two years. In the meanwhile the work of the institution will be carried on as usual in its present quarters, as it has been stipulated that the purchasers shall not take possession until the new buildings are ready for occupancy. In order to have incorporated in these the most approved modern features, Dr. Wachsmann, the medical superintendent of the home, has recently made a study of similar institutions in Berlin and other European cities, and in making the plans he and the building committee will have the valued assistance of Dr. S. S. Goldwater, the superintendent of the fine new Mount Sinai Hospital.

THE TUBERCULOSIS PREVENTORIUM FOR CHILDREN. — Contributing to the development of the Tuberculosis Preventorium for Children, which last April was removed from Lakewood to Farmingdale, N. J., the estate of Albert Brisbane, through Arthur Brisbane, has presented to the institution 64 acres of land and a free lease for twenty-five years of the Windsor stock farm adjoining, which comprises 240 acres under cultivation. As the physicians and architects of the preventorium found it necessary to have twenty acres more to obtain an ideal site, Mr. Brisbane has just bought an adjoining farm of 104 acres, to be able to provide the twenty additional acres desired. The total gift, therefore, comprises 84 acres in fee simple and 240 acres on a free lease for twenty-five years. He has also presented to the preventorium cows, wagons, furniture and other accessories. Nathan Strauss has already contributed $50,000 for model buildings to be constructed on the farm, while the Board of Health Auxiliary connected with the Association of Tuberculosis Clinics has subscribed $4,500 to build an additional open shack, for which it will select the children. The auxiliary has also subscribed for the support of the shack. To complete the plans to care for 400 children at a time, the preventorium will require $50,000 more for buildings and additional memberships yielding $85,000 a year. This institution, which, it will be remembered, takes only children who have not yet contracted tuberculosis, but whose condition indicates that they would readily fall victims to the disease, has already been successful in 212 children, aged from four to fourteen years, the average stay being about three months and the gain in weight from four to sixteen pounds.

Current Literature.

MEDICAL RECORD.

Nov. 5, 1910.

1. *STEIN, J. B. *The Ehrlich-Hata (606) Preparation (Therapia Sterilisans Magna). A Review of Some of the Reports made by German and French Physicians upon the Treatment of Syphilis by this Preparation.*
2. ABBE, R. *Custodianship of the Watch and Bible of Dr. Benjamin Rush, with Biographical Notes.*
3. BUGBEE, H. G. *Complete Subparietal Rupture of the Kidney, with Report of a Case.*
4. BARNES, G. E. *The Nonentity of Acute Dilatation of the Stomach.*
5. SCOTT, C. D. *Report of Two Cases of Tetanus following Vaccination.*
6. ABRAMS, A. *Asthma and the Lung Reflexes of Abrams.*

1. Stein reviews the reports of a number of German and French clinicians on the treatment of syphilis with "606." The reaction following injection varies greatly in severity; its important characteristics are pain radiating to the back and legs, local inflammation at the site of injection, fever (as high as 102.°5), headache, nausea and vomiting, tormenting thirst, diarrhea (not constant) and skin eruptions, especially a reddening and swelling of the luetic macules and papules (the so-called Herxheimer reaction).

Siesskind found that the spirochetes usually disappeared from lesions in from twenty-four to thirty-six hours after injection, but occasionally persisted for six or seven days. Before disappearance their vitality is greatly compromised, as indicated by their swollen appearance, diminished motility and loss of characteristic refringence. Evidence on the behavior of the Wassermann reaction under "606" is not convincing. Emery says that it slowly and progressively disappears without the oscillation encountered in mercurial cures. Hoppe and Schreiber observed that after fifty days 84.6% of their cases previously positive had become negative. The earliest the reaction was negative was after four days, the latest after seventy days.

Alt treated a number of primary lesions with a single injection (0.3 gm.) with immediate and astonishing results. The initial chancre with its induration showed marked retrogression after a few days. Mucous patches, eroding syphilides and other secondary manifestations disappeared in from twelve to thirty-six hours. An enormous gummatous ulcer of the leg was more than half healed five days after injection (Ehrlich). Remarkable results are reported in visceral lues and in hereditary syphilis, also in syphilis of the nervous system (Ehrlich forbids the use of the drug in the latter).

Blaschko gives the following indications for "606": (1) Lesions refractory to mercury; (2) relapse immediately following mercury "cure"; (3) continual relapses; (4) idiosyncrasy toward mercury; (5) malignant syphilis with destructive and dangerous lesions; (6) the appearance of a chancre in a first attack of syphilis. Contra-indications are old age, affections other than syphilis of the kidney, heart, liver, spleen or lung, advanced aneuryam, optic neuritis, grave cerebral lues. [L. D. C.]

10. *Hough, W. H., and Lafora, G. R. *The Cerebrospinal Fluid in Acute Anterior Poliomyelitis.*

10. Hough and Lafora give out a preliminary report of their findings in the cerebrospinal fluid of eleven cases of acute anterior poliomyelitis occurring in Washington, D. C., last summer. In all the cases the fluid was perfectly clear, in most of them the pressure was slightly increased, the protein content was increased and there was a moderate pleocytosis. In three cases examined during the first stages of the disease there was observed the highest proportion of polymorphonuclears (18% in one of them). The polynuclears disappeared after the fifth or sixth day of the disease through the phagocytic activity of the macrophages, which latter sometimes contained twenty or more chromatin bodies, probably the remains of the leucocytes. These chromatin bodies resembled morphologically the bodies described in certain protozoan diseases affecting the nervous system, e. g., the Leishman-Donovan bodies of kala-azar and the Mott bodies of Jinga trypanosomiasis. Late in the disease there were observed many lymphocytes, some plasma cells, a few macrophages and occasionally mast cells. The writers consider the similarity in histopathology of the spinal cord and fluid of anterior poliomyelitis and some protozoan diseases affecting the nervous system an argument in favor of the protozoan nature of the virus of poliomyelitis. [L. D. C.]

3. Pusey thinks that of all the remedies used internally for cancer, arsenic is the only one of possible benefit. He believes that all early cases are by no means suitable for excision. The chief danger of the knife is incomplete removal. The superficial caustics, such as phenol and silver nitrate, are dangerous because they really do not destroy deeply. Pyoktamin favors epidermisation and is often harmful. He also advises against curettage, electrolysis and liquid air as suitable only in a very limited type of case. He is a firm believer in the beneficial action of arsenious acid in 50 or 75% mixture with 50 or 25% powdered acacia and water. Radium he considers no more efficient than well-applied x-ray, which, however, he advocates for certain types of superficial cases.

7. Baar found that ether narcosis had no influence on the excretion of indican, but in all operations in which there was cutting or rough handling of the intestines, as in entero-enterostomies, there was excessive excretion of indican in the urine for a week or more following the injury. Moderate handling of the intestines during the course of an ordinary abdominal operation had no influence. He explains this by stating that trauma impairs the absorptive powers of the mucosa and thereby increasing intestinal putrefaction. An analogous condition exists often in colitis and in extensive enteroptosis in which we find increased indicanuria.

8. Post and Nicoll carried on a series of extensive experiments to determine the efficiency of the various germicides, and conclude as follows: Argyrol and protargol are not so active in concentrated solutions as ordinary silver nitrate in 1 to 5,000 or even 1 to 10,000 solution. Corrosive sublimate is slow of action, — over thirty minutes, — but is effective even in high dilutions. Creolin, lysol and phenol are very ineffective under thirty minutes. Five per cent phenol is, however, very effective in less than one minute. Iodine is effective in less than one minute. Formaldehyde is slow of action in 1 or 2% solution. Alcohol is effective in solutions of 50% or higher. Boric acid in saturated solution is non-effective even after twenty hours, also potassium chlorate. Glycerine has almost no germicidal power. The same is true of distilled water. [E. H. R.]

7. BUCHANAN, R. E., AND TRUAX, R. *Non-Inheritance of Impressed Variations in Streptococcus Lacticus.*
8. *TUNNICLIFF, R. *Observations on the Anti-infectious Power of the Blood of Infants.*

4. Holm and Gardner have investigated certain proprietary disinfection outfits in regard to their loss of formaldehyde, their power to penetrate, and their efficiency as disinfectants. They found that most of the products they examined were ineffective bactericides when used as recommended, and that in many of them there was considerable loss of formaldehyde.

8. The writer estimated the opsonic indices and phagocytic activity of a series of babies, and contrasted these with similar estimations in adults. She concludes that although at birth babies' resistance to infection as measured in these two ways is only a little below that of adults, the anti-infectious power rapidly falls and does not approach that of adults until the third year is reached. [G. G. S.]

4. HORNE, W. E. *Ehrlich-Hata "606."*

3. Pasteur describes a condition which he calls "active lobar collapse of the lung." This, which frequently occurs in fatal cases of diphtheria, when there is death from paralysis of respiration, according to the writer is a not uncommon sequel to severe abdominal operations where there is paralysis of the diaphragm and lower muscles of respiration. The collapse is usually of the lower lobes. The onset of an attack of this sort is usually sudden, but not always so. There is sudden dyspnea and cyanosis, pain, diminished breath sounds over the affected side and exaggerated breathing over the sound side. One of the most striking signs is the shifting of the apex beat toward the affected side. Another feature of some importance is the rapid disappearance of the symptoms and the return of the chest to normal. He cites several illustrative cases. [J. B. H.]

9. GUYENOT. *Radium and Radio-Activity.*

2. Lister presents an elaborate series of tables giving the mortality from tuberculosis in the various occupations, dusty, sedentary and otherwise, and draws conclusions from them. Of more interest, however, are his remarks upon the anti-tuberculosis campaign in general. The treatment of early cases and isolation of advanced cases is, in his opinion, only a small part of what must be done. A regular and systematic inspection of all employees and of school children is essential. Teaching as regards health among the poor and the regulation and supervision of dangerous occupations are all-important. A knowledge of sanatorium methods must be spread broadcast. The lessons of the sanatorium must be taught and enforced in the home and in the work shop. [J. B. H.]

4. Wakeling describes "sand-fly fever" as a non-fatal three-days' fever with a week's convalescence due to the bite of the fly, Phlebotomus papatarii. It exists in

Egypt, part of Austria, Malta and in Italy. The symptoms, aside from the bite itself, are tiredness, loss of appetite, malaise, headache, aching, temperature up to 104° F., and later well-marked anemia and loss of sight. There is a tendency to inflammation of sigmoid and joint cavities. The treatment is purely preventive.

8. Gauvain, in addition to describing the ordinary methods and his own of treating tuberculous caries of the spine, urges the need of medical attention to the child itself; he emphasizes the frequent neglect in educating such cripples and urges that this go hand in hand with treatment. This can be done better by especially selected and trained nurses than by any one else.

10. Box summarizes his ideas as to the treatment of colon infections of the urinary tract in children as follows: (1) Sufficient potassium citrate to make and keep the urine alkaline; (2) treatment by urinary antiseptics; and (3) treatment by serums and vaccines. Acute cases can be satisfactorily treated with potassum citrate alone. Chronic cases he finds very obstinate and resistent to all forms of treatment.

Pardoe, discussing this subject, believes that colon vaccines and other vaccines are of the greatest value in chronic infections.

12. D'Espine describes a sign which he considers of the greatest value in the early diagnosis of tuberculous bronchial glands. This sign is based on auscultation of changes in the breath and voice sounds at the level of the seventh cervical or first dorsal vertebra. When the child speaks in a low voice, the voice is accompanied by an added whispering sound localized to one or two vertebræ. There is also a bronchial quality of the respiration over this area. There may be dullness at this area associated with dullness at the level of the manubrium. The absence of râles and the presence of normal sounds at the apices will help to confirm the diagnosis. [J. B. H.]

Deutsche Medizinische Wochenschrift. No. 41.

Oct. 13, 1910.

This whole number of the journal is given up to papers on the treatment of syphilis with Ehrlich's preparation 606. These papers were presented at the eighty-second congress of German scientists and physicians which was held at Königsberg on Sept. 20, 1910.

The papers were by Drs. Neisser, Ehrlich, K. Alt, Schreiber, Iversen, Wechselmann, Orth, Miekley, Uhlenmuth, M. Margulies, C. Stern, W. Scholtz, A. J. Grünfeld, L. Michaelis, R. Volk and B. Lipschütz, Dohi, Grouven and others.

The papers by Neisser and Ehrlich cover the whole subject of the treatment of syphilis with this new preparation both from a practical and theoretical point of view. Ehrlich concludes by stating that the foundations are now safely laid; it remains for experience to decide on the value of the preparation. The other papers are on points of technic or personal experience with the drug. [C. F., Jr.]

17. Teske, H. *Paradoxical Movement of the Diaphragm.*
18. Köhler, F. *Diagnosis of Pulmonay Tuberculosis.* (Concluded.)

1. Enderlen discusses the technic of vessel surgery and then sets forth his indications for transfusion. He recommends it in severe losses of blood following injury, operation, childbirth and gastric ulcer, and for poisoning with illuminating gas. He advises against it in severe infections, tuberculosis, leukemia, and pernicious anemia, but does not give his reasons in detail.

Borst repeats the laws of organ transplantation established by others: that the transplanted organ must be fastened as soon as possible on to its source of nourishment and that if it is to survive long it must also receive early the stimulus to function. To these laws he adds that biochemical similarity of the individuals is of great importance. [G. C. S.]

2. Steinert reports important observations bearing on the etiology of endocarditis, and especially of the subacute forms. He disagrees with Schottmüller on several clinical points. In summarising he says that endocarditis lenta (subacute endocarditis, Schottmüller) may be caused not only by strepto. viridans, but also, under certain circumstances, by non-hemolytic streptococci; that these organisms, including viridans, may cause acute septic infections; that the chronic septic endocarditis occurs only in rheumatic patients, most of whom have an old endocarditis; and that the subjects of acute endocarditis have no rheumatic history. The writer then raises the question whether in a person once attacked by rheumatism an allergy may arise toward streptococci. [G. C. S.]

    LOTSCH, F. *An Apparatus for Forced Pressure Narcosis.*
    RIESE, H. *Actinomycosis of the Abdominl Wall due to a Splinter of Wood.*

1. Rotter's article presents a number of statistics concerning the mortality of peritonitis, both from his own experience and from that of others, and endeavors to find the cause for a higher mortality in certain series of cases. He concludes that neither the conditions of intra-abdominal pressure nor the kinds of drainage used influence the results, but that the difference in mortality is due to a difference in the type of cases from which a certain clinic draws its statistics.

An interesting point in Rotter's paper is the good results which he reports following closure of the abdominal wound, without drainage, in operations upon the gall bladder, even when pus has been spilled about the neighborhood of the liver.

3. Neuber reviews briefly the views which have been held as to the proper treatment of tuberculosis of the hip, and says that opinion has swung again to favor operative treatment. He then gives his technic for excision of the head of the femur, claiming for cases treated in that way an excellent result. Briefly, his procedure is as follows: A skin incision is made from anterior inferior spine of ilium downwards and inwards. Sartorius and long head of rectus femoris are cut near their origin; iliacus and anterior crural nerve are retracted inwards, thus exposing the anterior aspect of the capsule. This is opened, the head of the femur cut off with a Gigli saw, and the stump rotated forwards so it may be trimmed into the rough semblance of a head. The acetabulum is then cleared out, the stump replaced and the wound thoroughly irrigated with 5% formalin soap. Then the joint cavity is filled with 5% iodoform emulsion, a wick of vioform gauze led to the opening in the capsule, which has been sutured, and the wound closed to the wick. The leg is put up in strong abduction, with pressure over the hip.

5. In his article on ileocecal tuberculosis Eschenbach states that, excepting only the peritoneum, the cecum is the most frequently attacked viscus in the abdominal cavity. His experience covered 27 cases, of which 15 were in patients less than twenty years old. In 8 of these cases, the process seemed certainly to be primary in the intestine, for neither before nor after operation were signs of disease found in the lungs. Of the main symptoms of intestinal tuberculosis, i. e., tumor, mucus and blood in the stools, and stenosis, tumor was the only constant sign. Three had stenosis; 9, diarrhea. No case without lung involvement had fever. The treatment of these cases by excision of the affected part, followed by end-to-side or side-to-side anastomosis, was followed by a mortality of about 30%, due mostly to diffuse peritonitis. Eschenbach attributes much of this to the custom of leading gauze wicks to the site of suture; he now attempts to reinforce all such weak spots with a peritoneal flap, and sew the abdomen up tight. [G. G. S.]

BULLETTINO DELLE SCIENZE MEDICHE.

MAY, 1910.

1. *RUATA, G. O. *The So-Called Ozonifacient Compounds.*
2. BELLEI, G. *Some Notes on the Importance of Industrial Hygiene.*

1. From a chemical study and analysis of various essential oils and "ozonized" commercial products, Ruata concludes that such preparations never really liberate ozone, and that therefore their supposed hygienic value as germicides and deodorants is purely illusory. [R. M. C.]

JUNE, 1910.

1. RUATA, G. O. *The Luminosity of Certain Glasses.*
2. LUSSANA, F. *Action of Alanin on the Heart.*
3. *PUNTONI, V. *The Biologic Diagnosis of Echinococcus Cysts.*

3. From an extensive comparative study of the blood of cattle and of human beings with echinococcus cysts, Puntoni concludes that it affords excellent means for confirming the diagnosis of hydatid disease. The alexin reaction of Bordet and Gengou he believes is the most reliable, though technically very difficult. Next in value are eosinophilia and the precipitin reaction, which in his hands gave 78.4% of positive results. Anaphylaxis he does not consider practically available at present for diagnostic purposes. He believes that the biologic diagnosis of echinococcus should not be based on any one of these procedures, but that they should all be used to elucidate cases clinically obscure. [R. M. G.]

JULY, 1910.

2. *CANTELLI, O. *A Methodical Study of Certain Substances in the Urine, of the So-Called Oxyglycoproteid Group, and their Importance as Indication of Renal Lesion.*
3. *RUATA, M. *Ozone as a Gaseous Disinfectant.*
4. BOSELLINI, P. L. *Lymphodermia and Mycosis Fungoides.* (To be continued.)
5. AVONI, A. *The Disinfection of the Hands in Surgery.*
6. MODONESI, F. *Traumatic Psychoneurosis.*

2. Cantelli reports four cases, from an examination of the urine in which he concludes that the presence of para-, hypo- and glyco-xanthin in the urine indicates renal lesions, even in cases in which albumin is constantly absent.

3. The writer reports her experimental researches on ozone as a bactericide of the following organisms: Eberth's bacillus, colon bacillus, staphylococcus, B. fluorescens, B. prodigiosus, B. proteus vulgaris, diphtheria bacillus, cholera vibrio, and concludes it to be of relatively little value. [R. M. G.]

Miscellany.

"PNEUMONIC PLAGUE" IN ENGLAND.

During the past three weeks the daily press has contained occasional rather startling accounts of a so-called "pneumonic plague," said to be prevalent in the county of Suffolk, England. The disease, which is stated, though evidently without obvious authority, to be identical with the Black Death of 1348, is described as a fulminating pneumonia, causing death in a few days. Four cases appeared in September in the village of Freston, four miles from Ipswich, and all died. Since then no more human infections have been reported, but it was observed that rats, cats and rabbits were dying in large numbers in the vicinity with similar symptoms. From the fear of further spread of the disease through their agency has resulted an extensive popular campaign of extermination against small animals. Professional ratcatchers are said to have flocked to the county from all parts of England and to be reaping rich rewards from householders and proprietors of landed estates for destruction of thousands of cats, hares, rats and small rodents. Notices have been posted warning all persons not to touch any dead animal or to use the flesh of rabbits for food. The county of Suffolk includes the Orwell Peninsula, between the rivers Orwell and Stour, which is a great shipping district. Its chief city and seaport, Ipswich, which contains forty acres of dockyards, abounding in rats, is believed to have been the point of entry of the infection, through rats on grain-vessels from Odessa. Whatever the truth of the case, which in the absence of official medical statement and bacteriologic verification must for the present remain *sub judice*, the exterminative zeal of the inhabitants will at least have the advantage of ridding Suffolk of many undesirable vermin.

Correspondence.

"SUCCESS IN ATHLETIC SPORTS."

Cambridge, Mass., Nov. 12, 1910.

Mr. Editor: An editorial in the Journal of Nov. 3 relating to physical training seems to me to be a most unusual combination of broad physiologic wisdom and of (certainly unintended) injustice to the leader of American physical education. The algebraic sum of the editorial we need not try to specify!

It surely is a satisfaction to every physiologist (however the Harvard Athletic Association trainers and "rooters" may feel about it) to have an editor of the influential Journal pronounce the male trained athlete "an artefact, a man unnaturally developed to make an abnormal physical exertion"; to have an editor emphasize that "discipline of temperament is worth more than specific physical training"; and to have him remind his Journal readers of the importance of the mental factor in training for general vital efficiency. Certainly it were hard to imagine a *worse* condition of athletics than one in which a small minority are over-trained and thereby weakened for life, while the great essential majority who need it most get no efficient exercise or none plus nervous excitement, which makes matters worse by far. When the athletic associations in some of the universities begin to realize this thing and employ scientists rather than lawyers and ticket agents to manage their affairs, the mass of the students for whom they (nominally) exist will reap a surpassing benefit. At present sometimes luxury and extravagance leave no inclination for any utilitarian benefit to the student-body, which serves none the less as the scapegoat year after year.

But the high tone of the wisdom in this latter part of the editorial in question makes all the more unfortunate in a way the injustice done Dr. Dudley Sargent in the statement that he ascribes the "usual superiority of women over men in swimming" to "their better conservation of heat, owing to their usual greater proportion of adipose in proportion to the body-weight and bulk." However conspicuous this fat-factor may be in the case of Rose Pitonoff (and the present writer can testify to its unusual nature), Dr. Sargent never dreamed, we may be sure, of suggesting it as a cause of her extraordinary swimming feat of last summer (twelve miles in water that in places was as cold as 49° F.) and without fatigue. Indeed, in his address last fall before the Academy he expressly thus summarized the "factors that made it possible for Miss Pitonoff to accomplish this remarkable athletic performance": "The quick metabolism of youth; less body surface for radiation in proportion to weight than most girls of her age; muscles covered with a layer of fat; favorable anatomic structure; slow returning circulation; peculiar stroke; prolonged practice in swimming; unemotional nature; good habits of living supplemented by high moral courage, steadfastness of purpose and a determination to accomplish the object in view. All these desirable qualities were greatly aided by favorable circumstances, good training and skillful piloting." Here explicitly are *thirteen* highly instructive reasons for her success, of which the "layer of fat" is but *one*. Thus it is that the good sense and learning of an expert has received unintentional depreciation at your hands. If anything, he has underestimated this fat factor rather than overestimated it, as any one experienced in such matters who had seen Miss Pitonoff would be apt indeed to think. At any rate, the first part of the editorial in question misrepresents the facts and I write "in the interests of fair play," however little Dr. Sargent's reputation for good judgment might suffer from such editorial mistakes.

With great respect,

George V. N. Dearborn, M.D.

Post-scriptum. Since the above was written and mailed a letter has been received from Charles B. Durborow, one of the contestants in last summer's swim to Boston Light. He is a clerk in the First National Bank of Philadelphia, but "during the present year has swum 490 miles, rowed 1,967, and canoed 837," while last summer he swam from Philadelphia to Chester, about 33 miles, in twelve hours and forty-four minutes. He writes: "I tried the Boston swim late in August; in fact, I was determined to go to the Light and back, but I was not prepared for that awful cold. . . . I swam to abreast of Deer Light in 3.38 when the cold forced me to stop. I was under weight and over trained and not prepared. . . . I feel sure I could not stand the cold long enough for a round trip."

The somewhat striking coincidence of this unexpected letter with the ideas expressed in the above letter is obvious. Surely there are more factors in athletic (as in vital) efficiency than the majority of trainers and of physiologists are apt to realize. Not only in water but on land, the body heat relations have much to teach us.

G. V. N. D.

LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND OTHER OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED NOV. 2, 1910.

GLENNAN, A. H., assistant surgeon-general. Granted thirty days' leave of absence from Oct. 1, 1910, on account of sickness.

PETTUS, W. J., assistant surgeon-general. Leave of absence granted for one month and fifteen days from Aug. 29, 1910, amended to read one month and five days from Aug. 29, 1910.

WHITE, J. H., surgeon. Detailed to represent the Service at the next meeting of the Southern Medical Association, to be held in Nashville, Tenn., Nov. 8–10, 1910. Oct. 27, 1910.

YOUNG, G. B., surgeon. Bureau order of Oct. 9, 1910, relative to detail to represent Service at the annual meeting of military surgeons, revoked. Oct. 27, 1910.

LAVINDER, C. H., passed assistant surgeon. Detailed to represent the Service at the annual meeting of the Ohio Valley Medical Association, to be held in Evansville, Ind., Nov. 9–10, 1910. Oct. 27, 1910.

MCLAUGHLIN, A. J., passed assistant surgeon. Detailed to attend the annual meeting of the Association of Military Surgeons, to be held in Richmond, Va., Nov. 1–4, 1910. Oct. 28, 1910.

RUCKER, W. C., passed assistant surgeon. Detailed to attend the annual meeting of the Association of Military Surgeons, to be held in Richmond, Va., Nov. 1–4, 1910. Oct. 28, 1910.

CREEL, R. H., passed assistant surgeon. Relieved from duty on United States Revenue Cutter "Tahoma," and directed to proceed to Chicago, Ill., and report to the medical officer in command for duty. Oct. 25, 1910.

TURNIPSEED, D. C., assistant surgeon. Relieved from duty on United States Revenue Cutter "Perry," and directed to proceed to San Francisco, Cal., and report to Passed Assistant Surgeon M. W. Glover for duty. Oct. 25, 1910.

BELL, CHARLES, acting assistant surgeon. Granted thirty days' leave of absence from Nov. 26, 1910.

CLYBORNE, A. B., acting assistant surgeon. Granted seven days' leave of absence from Oct. 25, 1910, under paragraph 210, Service Regulations.

HOUGHTON, M. W., acting assistant surgeon. Granted five days' leave of absence from Oct. 31, 1910.

NAULTY, C. W., JR., acting assistant surgeon. Granted one day's leave of absence, Nov. 1, 1910.

SAFFORD, M. V., acting assistant surgeon. Granted three days' leave of absence from Oct. 28, 1910, under paragraph 210, Service Regulations.

STEVENSON, J. W., acting assistant surgeon. Granted two months' leave of absence without pay from Nov. 1, 1910.

THURSTON, E. J., pharmacist. Granted three days' leave of absence from Oct. 24, 1910, under paragraph 210, Service Regulations.

WOLFE, J. A., pharmacist. Granted one day's leave of absence, Oct. 22, 1910, under paragraph 210, Service Regulations.

BOARDS CONVENED.

Board of medical officers convened to meet at the call of the chairman at Port Townsend, Wash., for the purpose of conducting a physical examination of an officer of the Revenue Cutter Service. Detail for the board: Surgeon J. B. Stoner, chairman; Surgeon J. H. Oakley, recorder. Oct. 26, 1910.

Board of medical officers convened to meet at the Quarantine Office, Honolulu, Hawaii, Nov. 21, 1910, for the purpose of conducting a physical examination of an officer of the Revenue Cutter Service. Detail for the board: Passed Assistant Surgeon Carl Ramus, chairman; Assistant Surgeon E. R. Marshall, recorder. Oct. 27, 1910.

Board of medical officers convened to meet at the Marine Hospital, Baltimore, Md., Nov. 21, 1910, for the purpose of conducting a physical examination of an officer of the Revenue Cutter Service. Detail for the board: Surgeon W. P. McIntosh, chairman; Passed Assistant Surgeon Dunlop Moore, recorder. Oct. 27, 1910.

RECENT DEATHS.

HENRY WURTZ, A.B., Ph.D., who died last week in Brooklyn, N. Y., was at one time professor of chemistry in the National Medical College in Washington. He was born at Easton, Pa., on June 5, 1826, graduated from Princeton College, and later received an honorary doctorate in philosophy from the Stevens Institute of Technology at Hoboken, N. J. He served for a time as chemical examiner in the United States Patent Office, and was author of numerous chemical writings. He discovered and described *huntilite*, "a silver arsenide occurring with metallic silver at Silver Islet in Lake Superior, Michigan," and for him was named the mineral *wurtzilite*, "a solid bitumen found in the Vintah Mountains, Utah. He is survived by a daughter and four sons.

DR. FRANK NEWELL LEWIS, a well-known ophthalmologist of New York, died on Nov. 13, after a brief illness. He was born in Burlington, Vt., in 1857, of Welsh parentage, his father being Dr. James Lewis. He was graduated from the academic department of the University of Vermont in 1875, and from the medical department of the University in 1882. After additional study in Europe he served as interne at the Mary Fletcher Hospital in Burlington, and then began practice in New York. He later became professor of diseases of the eye at the New York Post-Graduate Medical School and afterwards executive surgeon at the Manhattan Eye, Ear and Throat Hospital. For a number of years he was associated with the late Dr. D. B. St. John Roosa.

REMARKS ON THE TECHNIC OF OPERATIONS FOR STONE IN THE URETER.*

BY HUGH CABOT, M.D., BOSTON,

Surgeon in Charge, Genito-Urinary Out-Patient Department, Massachusetts General Hospital.

It is not my intention to burden you with a general discussion of the technic of operations for stone in the ureter, but as the position of the operation in surgery has changed rapidly within the last few years on account of the great accuracy of diagnosis, there are certain points of technic to which I wish to invite your attention.

INCISIONS FOR THE EXPOSURE OF THE URETER.

With recent advances in the technic of ureteral catheterization and radiography, it is possible in the vast majority of cases to know beforehand in what portion of the ureter a stone is situated and plan the operation to reach this portion of the ureter, rather than to expose a large portion of the ureter for exploratory purposes. A great majority of stones lodge at one of three points.

1. The physiological constriction just below the pelvis of the kidney, about on a level of the lower pole of the kidney.

2. At the brim of the true pelvis where the ureter crosses the iliac vessels.

3. In the lower two inches of the ureter, near its point of entrance into the bladder wall.

The ureter in the first situation is, I believe, best reached by an oblique muscle-splitting incision, starting at about the tip of the twelfth rib and running downward and forward to a point about midway between the anterior superior spine of the ilium and the umbilicus. The fibers of the external oblique are separated in line of the incision, those of the internal oblique and transversalis practically at right angles to the incision. If the separation of the muscles is freely made, good access is obtained to the upper half of the ureter. After the muscles have been separated, the peritoneum is pushed back and the ureter readily found lying upon the psoas muscle, though its tendency to be turned up with the peritoneum should not be forgotten.

Stones situated at the brim of the pelvis may be conveniently reached by an incision in the same line as the one above described, but beginning where the other stopped at a point nearly midway between the anterior superior spine of the ilium and umbilicus and continued downward to the junction of the inner and middle thirds of Poupart's ligament. Here again the peritoneum may be pushed back and the ureter readily found at the point where it crosses the bifurcation of the common iliac artery.

For stones in the lowest portion of the ureter, the incision advised by Gibson is particularly suitable. This incision starts in the middle line about a finger's breadth above the pubes, running horizontally outward nearly parallel to Poupart's ligament at first and curving rather sharply upward at its mid-point to end about opposite to the anterior superior spine of the ilium. The aponeurosis of the external oblique and internal oblique is divided in the line of the incision, and at the outer portion of the incision a few fibers of the internal oblique may have to be cut across. The upper flap is then retracted, the external border of the rectus muscle identified and the fascia of the transveralis divided by a vertical incision, close to and parallel to the rectus, that is, at right angles to the original incision. The peritoneum is then stripped back, and with good retraction, and the patient in the Trendelenburg position, an excellent exposure of the base of the bladder and lower portion of the ureter is obtained.

The incision seems to me much superior to the curved incision commonly used, and in practice I have found the exposure all that could be asked for.

REMOVAL OF THE CALCULUS.

Most writers upon this question, and notably Albarran and Jeanbrau, whose recent contributions are of the greatest value, advise incising the ureter upon the stone. The point to be gained is, of course, the removal of the calculus with the least damage to the ureter and to leave the tissues in such a condition that subsequent suture of the ureter may be done without danger of leakage. They point out that the attempt to draw the stone up the ureter is likely to subject it to trauma, which will lower its resistance and result in sloughing, with the possible production of stricture. Their reasoning on this point does not seem to me sound. The point at which the stone is arrested is usually a physiological narrowing; the presence of the stone has generally resulted in inflammation, frequently in ulceration of the ureter. The ureter below the stone is of normal, or less than normal, caliber, while above the stone it is practically always dilated. I believe that incision on the stone in the ulcerated tissue is almost certain to result in some sloughing of the tissue, and that the already existing tendency to stricture is increased by the fact that suture further narrows the ureter and that the sutures are likely to cut through with further sloughing. In a word, I believe that this technic in difficult cases, particularly with an infected kidney, is likely to cause rather than prevent leakage and stricture of the ureter. As has already been noted, the ureter above the stone is generally dilated. It is safer to incise the ureter one or two inches above the stone, then with suitable forceps passed into this opening withdraw the stone and extract it through the incision. In my experience this has not resulted in notable trauma of the ureter, and though in two of the cases, the reports of which are subjoined, the stone was considerably impacted, no difficulty was experienced in dislodging it. The chief advantage of this method seems to me to lie in the greater security from subsequent leakage or stricture, whether or not sutures are employed. The dilatation of the ureter makes the application of the suture not only easier, but free from danger of narrowing the ureter. It is frequently possible

* Read at the meeting of the American Urological Association, June 6 and 7, 1910, at St. Louis, Mo.

to apply two layers of sutures without reducing the ureter even to its normal caliber.

THE PERMEABILITY OF THE URETER.

The failure to ascertain the permeability of the ureter at this time, and its freedom from other calculi, or from strictures, has been a potent source of unsatisfactory results. As Albarran has wisely pointed out, freedom of the ureter from obstruction is essential to success. This permeability may be ascertained by the use of bougies, or, better, by a small bougie-à-boule, which should be passed downward to the bladder and upward to the kidney. If stricture of the ureter is found, it must be relieved before the operation is finished, either by the internal ureterotomy of Albarran, or by some other method.

TREATMENT OF THE URETER AFTER EXTRACTION OF THE CALCULUS.

Until recent times, the only question here at issue was that of suture of the incision. Recently, however, Albarran and others of the French school have advocated the placing of an inlying catheter which would drain the kidney pelvis direct, and thus, in their opinion, favor wound healing. Albarran advises, though does not insist upon, its use in aseptic cases, but strongly urges its use in septic cases. Jeanbrau, in a recent monograph, advises its use only in septic cases. I believe the method to be largely without merit for the following reasons: The catheters which can be used without doing damage to the vesical orifice of the ureter are necessarily small, not larger than a 12 or 13 F. It is to be remembered that the ureter is almost habitually dilated, sometimes to considerable size. It is almost inconceivable that a catheter of this caliber, especially in septic cases, could drain the kidney pelvis so satisfactorily as to prevent the collection of pus and urine in the ureter outside of the catheter. More especially is this likely to occur where there is active suppuration and pus formation in the kidney. Our experience with inlying catheters in the urethra does not encourage the belief that their presence is not objectionable, as they undoubtedly favor infection. Should the catheter fail to drain completely, and the urine enter the ureter along the side of the catheter, great pressure will be brought to bear upon the incision in the ureter, which is likely to leak if no sutures have been used, and certain to produce strain upon the suture and sloughing if they have been employed. A catheter of this caliber fits very snugly in the vesical orifice of the ureter and considerable pressure must be exerted before the urine can be forced by the catheter. Should the catheter fail to drain, and leakage occur, all advantage of the catheter is lost and increased sloughing about the incision in the ureter is likely to result. Stress has been laid upon the value of the inlying ureteral catheter in cases of stricture of the ureter below the calculus. If its use is confined to these cases it may be of advantage, but our experience with stricture of the urethra does not encourage the belief that permanent results will be thus obtained.

DRAINAGE OF THE ABDOMINAL WOUND.

It has been the almost universal custom to put some drainage in the abdominal wound down to the point of suture in the ureter. It has been regarded as a form of insurance which could do little harm and might save troublesome complications should leakage occur. With this view one cannot but sympathize; on the other hand, it is not inconceivable that the use of drainage even in this way may favor leakage, as it undoubtedly does in cases of suture of the intestine, though it is admitted that the cases are not parallel.

In three recent cases, two of which were aseptic and one markedly infected, no drainage of any kind has been used and the wound has been closed in layers including the skin. While I am not prepared to advise this as a routine procedure, I would ask for it your consideration.

The following cases are submitted as tending to support my contention.

Mrs. A. K., thirty-four. First seen Jan. 9, 1909. Eight years ago had an attack of what was apparently renal colic in the left side, followed by the passage of a stone. No further trouble until six months ago when she had another attack of left-sided pain with nausea and vomiting. Pain, never very severe, lasted for a few days and disappeared. Two months ago another attack of similar character. Since that time has had more or less left-sided pain coming in attacks, but not enough to lay her up. Moderate frequency of micturition, amounting to twice at night. No known hematuria.

Examination negative except as below described. There was slight general abdominal tenderness, most marked on the left side along the course of the ureter and in the left costo-vertebral angle. By vagina there was marked tenderness to the left of the cervix, and it was thought that a mass could be felt in the region of the ureter. X-ray showed a stone in the left ureter about two inches above the bladder. Urine was normal, acid, 1,022, albumen slightest possible trace. Moderate sediment, consisting of pus and a few red blood corpuscles. At the time of entrance there was almost constant vomiting and considerable pain in the left groin. Operation was done about six hours after admission. An attempt was made to reach the stone through a vaginal incision, but it was so movable in the ureter that it could not be reached by this route. A six-inch incision was, therefore, made from the anterior superior spine on the left downward and inward parallel to Poupart's ligament, muscles separated and divided and ureter exposed near the brim of the pelvis. It was found dilated to the size of the finger and much thickened. Following it downward the stone could be felt. It was readily dislodged and pushed up the ureter to a point near the brim where the ureter was incised and the stone removed. The incision in the ureter was then closed with interrupted catgut sutures. A small cigarette drain placed to the point of suture. Wound closed about it in layers. Wound healed kindly without leakage. At the time of discharge from the hospital urine was normal, acid, 1,031. No albumen or sediment.

Feb. 1, 1910. The scar is firm, has had no symptoms from kidney or ureter, and urine is normal.

Mr. M. M. D., twenty-four. Entered hospital Feb. 16, 1910. Six years ago had an attack of painless hematuria lasting two days. Two years ago another attack of hematuria, also painless, but followed by the passage of three small calculi. Two months ago colicky pain in the right lower quadrant of the abdomen.

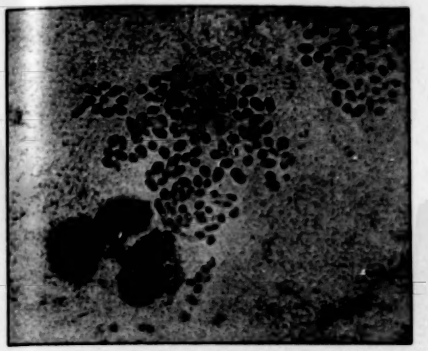

FIG. 1. Pneumococci. Pericardial exudate. 1500

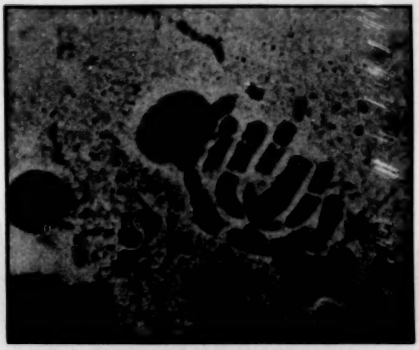

FIG. 4. Bacillus mucosus capsulatus, sputum, bronchitis. 1500.

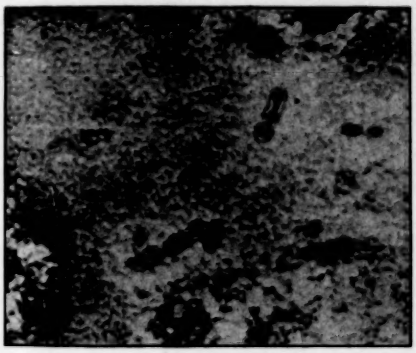

FIG. 2. Pneumococci smear from lung exudate, pneumonia. 2800.

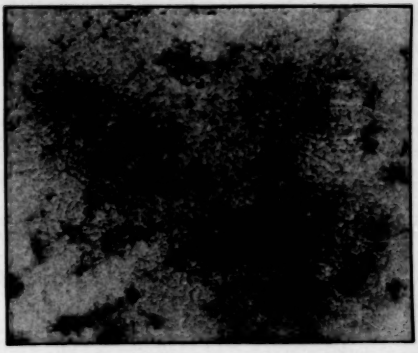

FIG. 5. Bacillus aerogenes capsulatus. Smear from spleen. Septicemia. 1500.

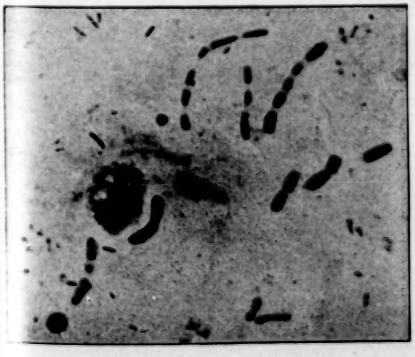

FIG. 3. Streptococcus mucosus capsulatus (pseudo-pneumococcus), sputum, bronchitis. 1500.

FIG. 6. Bacillus of anthrax. Smear from pustule. 1800.

Pain shooting to the right testis and penis. Since that time has had several such attacks, but no marked hematuria, though the urine has been smoky. Two weeks ago was laid up in bed for several days with a dull pain in the region of the cecum and was thought to have appendicitis.

Examination showed tenderness with some muscular spasm in the right lower quadrant of the abdomen, but was otherwise negative.

Cystoscopy showed a normal bladder with the orifice of the right ureter slightly larger than the left, but not otherwise abnormal. Normal urine from the left side, none from the right. Ureter catheter entered right ureter for 9½ cm., but could be passed no further. Several x-ray plates were negative. At operation the ureter was exposed at the brim of the pelvis by an oblique incision starting about two inches inside of the anterior superior spine and running downward and inward for about five inches. The peritoneum was pushed back, the ureter located and the stone felt just below the iliac vessels. A Crile clamp was placed upon the ureter to prevent urinary leakage, and the ureter incised at a point just above where it crossed the vessels and about 1½ inches above the stone. A pair of narrow-bladed forceps was then passed into the ureter, the stone grasped and readily removed. The wound in the ureter was closed with a single layer of interrupted 0 catgut sutures. The abdominal wound was closed in layers without drainage.

Patient last seen in May, 1910, when he was in good condition and had a normal urine.

Mr. C. C. B., forty-two. Entered hospital Feb. 25, 1910. Seven years ago had an attack of pain in the right loin and side. Hematuria for several days, followed by the passage of several small stones. Well until ten days ago, when he began to have pain in the right side similar to but not so severe as the previous attack. This was accompanied by moderate frequency of micturition, amounting to three to five times at night. No hematuria. Pain lasted two days and then disappeared, but the frequency of urination continued and the urine contained pus. It was for this he applied for treatment.

General physical examination negative. Series of good x-ray pictures was negative. The urine was pale, cloudy, alkaline, 1,013, albumen slightest possible trace, sediment, mostly pus with rare red blood corpuscles.

Cystoscopy showed bladder generally normal. Right ureteral orifice slightly thickened and slightly ulcerated. Ureter catheter enters the right ureter for 7 cm. A smaller catheter was then tried and passed 10 cm., but would go on further. Catheter passes up the left ureter freely and draws normal urine. Indigo-carmine excreted in nine minutes by left kidney, not at all by the right in an hour.

The position of the stone in this case was then demonstrated by taking an x-ray picture with the tube placed in an oblique position as described in a paper by Cabot and Dodd (Boston Medical and Surgical Journal). This patient was operated upon by the same method as that employed in the last case. The stone was much larger, and was found tightly impacted in the ureter at the point where it crosses the iliac vessels. There was moderate dilatation of the ureter above the stone. The ureter was occluded with a Crile clamp and opened about two inches above the stone. This was then grasped with forceps, dislodged without difficulty and removed. The wound in the ureter was closed with two layers of interrupted 0 catgut sutures. In spite of the infected condition of the kidney, the closure of the wound in the ureter seemed so secure that no drainage was used. The abdominal wound was closed in layers without drainage. Convalescence was entirely uneventful.

Patient was seen in May, 1910, and is now free from symptoms, though the urine is still slightly cloudy with pus, and it is not improbable that the damage to the kidney has been so great that its ultimate removal may be wise.

Mr. F. C. N., thirty-four.

Previous history unimportant except for a severe crushing accident involving the left hip four years ago. From this he recovered with a good deal of stiffness and some shortening of the leg. Three years ago passed a stone from his bladder which troubled him only in its passage through the urethra. There was no renal colic and no hematuria. Six months ago had an attack of renal colic with hematuria, no stone passed.

April 12, 1910. A severe attack of renal colic with hematuria. It was so severe that he was taken to the Emergency Hospital, where he remained over night. Since that time has had some grumbling pain in the left lower quadrant of the abdomen. No pain on urination.

Physical examination is totally negative. Urine shows slightest possible trace of albumen, moderate sediment, pus, round cells, moderate number of red blood corpuscles.

April 20. Cystoscopy shows a normal bladder and normal ureteral orifices. Ureter catheter enters 2 cm. in the left but will go no further. X-ray plates by Dr. Dodd negative for kidney region. On the left side about 1½ inches from the symphysis pubis is a definite shadow, probably in the left ureter. Operation advised.

April 25, operation. Anesthol and ether.

Curved incision from about one inch to the right of the symphysis pubis, about one inch above Poupart's ligament, following that line upward and outward to the region of the anterior superior spine on the left. External oblique fascia separated, fibers of the internal oblique divided. The fascia was then divided vertically at the outer border of the right rectus, thus forming a triangular flap (Gibson's incision). Peritoneum freed from iliac fossa and ureter exposed from the iliac vessels downward with some difficulty. Peritoneum torn just in front of the ureter. Ureter freed, held up by a loop of catgut, Crile clamp placed near the brim and the ureter opened about two inches above the bladder, where it was dilated to the size of a lead pencil. Probe passed into the opening could feel the stone about 1½ inches below. Stone picked up with some difficulty by means of a small straight clamp and extracted. Bougie passed to bladder without obstruction. Wound in ureter closed with two layers of 0 catgut. Abdominal wound closed in layers without drainage.

June, 1910. Patient has made an uneventful recovery.

A METHOD OF STAINING CAPSULATED BACTERIA IN BODY FLUIDS.

BY WILLIAM H. SMITH, M.D.

(From the Pathological Laboratory of the Massachusetts General Hospital.)

The following method of staining capsulated bacteria in body fluids is published in order that its real value may be determined. It has been found, during the past two years, in my hands, to bring more uniform results than any other method with which I am familiar.

In looking over some preparations of pneumonic exudate due to the Bacillus mucosus capsulatus, stained by Mallory's connective tissue stain, the well-marked staining of the capsule about the bacilli in the exudate was noted. Pre-

vious experience in staining the capsule about these micro-organisms in the exudate in other preparations, and its difficulty, led me to investigate why in this particular preparation, stained with Mallory's stain, the capsule should be so much clearer than in any of my other specimens.

The capsules about the micro-organisms were stained blue in the preparation above referred to, specimens of sputum, lung exudate, pleural and pericardial effusions were stained with Grübler's aniline blue in varying strength, but the capsules about the pneumococcus or streptococcus mucosus capsulatus present in the preparation did not stain. The same smears when stained by the aniline blue, orange G. phosphomolybdic acid combination did show capsules. It was then considered that the phosphomolybdic acid might be a factor, and, after repeated trials with phosphomolybdic acid of different strength, more uniform results were obtained. As a result of this investigation, the following method is recommended for staining capsulated bacteria in body fluids.

1. Make a thin smear from fresh sputum, lung, pleural or pericardial exudate.
2. Pass through flame.
3. Cover with 10% (ten per cent) aqueous solution of phosphomolybdic acid (Merck) four to five seconds.
4. Wash in water.

If the micro-organism is Gram-staining like the pneumococcus or streptococcus mucosus capsulatus, stain with,

5. Aniline oil gential violet, steaming one-quarter to one-half minute.
6. Wash in water.
7. Treat with Gram's solution of iodine, steam one-quarter to one-half minute.
8. Decolorize with 95% alcohol.
9. Wash in water.
10. Stain with 6% (six per cent) aqueous solution of eosin (Grübler's w. g.) one-half to one minute, warming gently.
11. Wash in water.
12. Wash in absolute alcohol.
13. Clear in xylol and mount in Canada balsam. The capsule will be found to be distinct, clear cut, eosin stained, about the Gram-stained micro-organism.

If the micro-organism is Gram-decolorizing, after covering the smear with phosphomolybdic acid and washing,

1. Stain with 6% (six per cent) aqueous solution of eosin one-half to one minute, warming gently.
2. Wash in water.
3. Counter stain with Loeffler's methylene blue one-quarter to one-half minute, warming gently.
4. Wash in absolute alcohol.
5. Clear in xylol and mount in Canada balsam. The capsule will appear eosin stained about the blue-stained micro-organism.

I am indebted to Dr. James Homer Wright for his frequent advice during the progress of the work, and to Mr. L. S. Brown for the photomicrographs which accompany the article.

CANCER OF THE SCROTUM.

BY ROBERT M. GREEN, M.D., BOSTON.

(Concluded from No. 20, p. 759.)

OGSTON, in an article on the "Local Effects of Crude Paraffin," in the *Edinburgh Medical Journal*, 1871, xvii, 544, says:

"The workmen engaged in this manufacture [of paraffin] have the skin over portions of their bodies, more especially of the hands and arms, but also of the feet and legs, brought daily for many hours at a time into contact with the paraffin shale, and with the oily matters mixed up with it, the result being an eruption of nodules and pimples on the skin so exposed, speedily breaking out on those who are for the first time engaged in it, lasting for a few weeks or months, and then generally diminishing or disappearing. In a few exceptional individuals the eruption does not disappear, but, assuming a chronic character, produces so marked and prolonged an affection of the skin that the general health becomes impaired and the cessation of this employment becomes a necessity. The appearances differ in the two classes of cases, acute and chronic, and, while the essential alterations in the skin remain the same, the presence of inflammatory action in the acute, and its absence in the chronic, forms leads to a marked distinction between the two, and admits of their being separately described.

"In the *acute* form of the eruption, which soon appears in those exposed to the influences of crude paraffin, the skin of the hands, wrists, arms, feet and legs becomes covered with a rash of bright red nodules, closely approximate to each other, and usually largest and most numerous on the wrists or wherever the dress tightly embraces the skin, the dorsal aspects of the parts being most severely affected, and the palms of the hands and soles of the feet enjoying a complete immunity. Similar nodules arise, though to a less extent, on the face, neck and other parts of the body to which the oily matters find access.

"On examining minutely the skin of those affected in this way, the following are the leading peculiarities of the eruption: The bright red nodules, hard to the touch, tender on pressure, varying little in size, which is about equal to that of a grain of barley, are of a rounded form and consist each of a single hair-follicle with the parts immediately surrounding it, which are inflamed, indurated and reddened. The hair emerges from the very summit of the nodule, and the orifice of the hair-follicle is much enlarged and easily visible to the naked eye as an aperture of a magnitude similar to that of a pinhole in a card. The dilatation extends to the deeper part of the follicle, which forms the kernel of the inflamed knot, the retention of its contents evidently contributing to the inflammatory induration around. The gaping mouth of the follicle exhibits masses of cast-off epithelial scales, dry and friable instead of greasy and tenacious; the nodule has little of the tendency to run on to suppuration observable in an ordinary *comedo*, and its contents cannot be

squeezed out. On the contrary, the redness and induration, after remaining for some little time, gradually diminish and finally disappear, leaving the hair-follicle enlarged and its mouth gaping so as to exhibit the retained epithelial masses, these latter being rendered more distinct by continued retention and accumulation of dirt. In fact, the *acute* form of the eruption consists of successive crops of these nodules, which are thus at the same time seen in all stages of their growth, full development and subsidence, while the skin between them, studded with the black gaping mouths of such follicles as have already passed through or are about to undergo the process, retains, contrary to what is observed in the chronic form of the malady, its natural pliancy and elasticity.

"In all paraffin-workers, patency and enlargement of the hair-follicles continue to some extent so long as they are engaged in this manufacture, and the black dots in the skin of their hands and face strike the eye of the observer at once, men with dark complexions and strong hair being especially deformed in this way, while fair complexions and light or reddish hair escape comparatively unaffected.

"A few exceptional individuals, with swarthy complexions and hairy skins, suffer so much from an exaggerated patency of the follicles that they are compelled to quit their occupation and seek a more suitable calling. When the disease assumes this *chronic* form it exhibits the following characteristics: The backs of the feet and toes, the dorsum of the hand and the backs of the fingers between but not over the joints exhibit a peculiar honeycombed appearance of the skin, which is elevated, thickened and inelastic, so as to prevent or render difficult and painful the flexion of the fingers and hand. These elevated honeycombed patches are of natural color and not inflamed (except where an isolated papule exhibits the appearance described under the acute form), but consist of densely-grouped arrays of hair-follicles, with the indurated cutis between and around them, the follicles packed with dry, brittle accumulations of epithelial scales so extensive as to be easily visible through the dilated mouths of the follicles, these latter being large enough to admit the extremity of an ordinary probe. The hairs themselves have disappeared from these patches, having probably become atrophic from the pressure of the epidermic masses, while cracks and bleeding fissures traverse the indurated parts, and in rare instances a follicular abscess gives variety to the picture. The knuckles of the fingers and toes, the palms of the hands and the soles of the feet remain unaffected by the disease. In the subject of the chronic malady the complexion is pale and the tongue foul, while the loss of flesh betrays the effects of the sleepless nights caused by the constant irritation and pain of the skin of the affected extremities.

"The *modus operandi* of the crude paraffin in producing these results seems to be as follows: The only matters in the shale, called 'blue oil,' when separated, are both penetrating in their properties and irritating to the skin; and, coming continually in contact with the epidermis, soak into the hair-follicles, where they create an irritation soon leading to induration and increased exfoliation of epithelial scales. This exfoliation is not counterbalanced by increased expulsion of the scales, owing doubtless partly to the large quantities cast off and partly to the usual fatty and lubricating substances mixed up with them, being dissolved out and removed by the 'blue oil,' thus leaving the brittle epidermic masses plugging the follicles and increasing the inflammatory irritation. (The palms of the hands, soles of the feet and knuckles of the fingers and toes — places supplied with sweat-glands but no hair-follicles — escape the irritation from the watery contents of the sudoriparous pores presenting an obstacle to the ingress of the oil.) After a time the hairs on the most exposed parts become atrophic and fall out, but the continued retention of the epithelial masses keeps up the process in the follicles and the induration of the surrounding skin.

"The workmen are in the habit of employing 'shale spirit' to wash the affected parts, whether with any beneficial effect is, I think, doubtful."

The pathology of scrotal cancer is brief; it is epithelioma of the squamous-celled type. In the section on tar and paraffin cancer in his "Surgical Pathology and Therapeutics," Warren says:

"An histological study of the irritated skin shows a growth of the lower layers of the epidermis and of the rete mucosum. The hair-follicles are frequently distended with masses of epidermic cells, and in the deep layers of the rete are found spots of brown pigment. Near the carcinomatous nodules the dividing-line between epidermis and the cutis becomes very irregular, and the interpapillary masses of cells are enlarged and irregular in shape. The skin shows also a small cell infiltration. When the zone of the cancer is reached, there are found enormous numbers of epidermic balls and a polymorphous-cell growth into the deep layers of the cutis. It is evident that we have to do here with a chronic irritation of the skin affecting its epithelial structures for a long time, producing at first hypertrophy of some of these structures, and finally a tendency to indefinite growth, as in cancer."

Bransby Cooper, in his course of surgical lectures at Guy's Hospital, in 1846–7, says:

"I cannot believe that the term 'cancer' is strictly appropriate to this disease; for although it is true that a patient who is the subject of this local affection must have a predisposition to its development, still few cases are recorded in which it has arisen from any other exciting cause than that produced by the irritation of soot. It may, however, be fairly conjectured that when a malignant diathesis prevails, the continued irritative influence of such a substance as soot may produce a malignant local development. Still, however, a mystery is involved in such a view; for as the whole surface of the body is more or less subjected to this source of irritation, it is difficult to understand why the scrotum more than any other part should so invariably become the seat

of the disease; to this, however, the answer may be that the rugous and delicate character of the skin, the size and number of the follicles with which it is furnished, and perhaps its pendulous position, and, being usually in a moist state, may tend to render it more than any part of the body susceptible to diseased action as the result of continued irritation. A very similar disease is prevalent in the West Indies, under the name of 'sun-wart'; this disease attacks the face in old people, and usually makes its appearance in the wrinkles and furrows which naturally harbor perspiration, and in which the follicles are larger and more numerous than in other parts. Chimney-sweepers' cancer is a very rare disease and is but seldom met with even in the class to whom it may be almost considered peculiar; soot, therefore, must be looked upon not as possessing any particular property of producing this carcinomatous affection, but as merely determining or exciting the action in individuals in whom there exists a malignant constitutional tendency."

In 1866, Curling, in his "Practical Treatise on the Diseases of the Testis and of the Spermatic Cord and Scrotum," page 592, says:

"The ulcer spreads towards its circumference widely and superficially, whilst in the center it burrows deeply, until in many instances it reaches the great vessels of the thigh, destroys their coats and causes death by hemorrhage."

On page 596, he cites a case of Sir William Fergusson's of scrotal epithelial cancer in a man who for many years had worked amongst guano.

On page 598 he reports the case of a sailor of forty-five who had been a chimneysweep as a boy, but for twenty-two years had followed the sea. He had a scrotal cancer of three years' duration.

On page 602, he cites a case of Paget's, a chimneysweep of sixty-six, who had a "cancer-wart" on each hand, and had had a scrotal cancer removed thirty-five years before.

At page 599 Curling further says:

"Chimneysweeper's cancer is a disease almost peculiar to this country. . . . Pit-coal, from which soot is produced, is only sparingly employed as fuel abroad, whilst in this country it is in almost universal use by all classes, and until recently our chimneys were cleansed by climbing-boys, who were consequently exposed from an early period of life to continued contact with soot. But these circumstances seem scarcely sufficient to account for the prevalence of epithelial cancer of the scrotum in England in comparison with other countries, without admitting the existence of a greater predisposition to the disease in the constitution of natives of this country."

He gives as further references:

Paget: Pathology. Richerand: Nosographie Chirurgicale, t. iv, p. 300. Russell: Observations on the Testicles, p. 98, Edinburgh, 1833.

Russell says: "Cases of the chimneysweeper's cancer occur frequently in the London hospitals though very seldom at the Royal Infirmary of Edinburgh.

Warren refers to Volkmann; Charles W. Allen to Andrews.

Richerand in his "Nosographie Chirurgicale," Paris, 1812, t. iv, p. 500.

"Pott parle de certains ulcères qui affectent le scrotum, chez les ramoneurs de Londres. Cette maladie, qu'il décrit sous le nom de cancer des ramoneurs, paroît endémique; on ne l'a point observée en France; et Rammazini, qui écrevoit en Italie sur les maladies des artisans, n'en fait mention dans aucun endroit de son estimable ouvrage. Sans doute que la nature particulière de la suie, dans un pays où l'on ne brûle guère que du charbon minéral, est la cause de ce genre d'affections."

Paget, in his "Surgical Pathology," Philadelphia, 1865, page 629, says:

"A . . . drily scaled or incrusted warty change of the cutis often . . . precedes the chimney-sweep's cancer; and I suspect that the true influence of the soot in this disease is not that its continued contact determines the growth of cancers, but . . . that it produces a state of skin which provides an apt locality for epithelial cancer in persons of a cancerous diathesis. How it does this I cannot imagine, but this is only one of many things unexplained in this strange disease; for the whole of the peculiarities of the chimney-sweep's cancer — its dependence on soot, while coal-dust is wholly inoperative (for the disease is unknown among colliers); its comparative frequency in England, especially in the large towns, while in other countries where soot is abundant it is hardly seen; its selection of the scrotum for its most frequent seat, — all these and many like facts in its history appear completely inexplicable. Still, it is certain that scaly or incrusted small warts . . . are very common in chimneysweeps. . . . Nor are such warts confined to the scrotum; they may exist on every part of the trunk and limbs; and I have seen sweeps so thickset with them that a hundred or more might have been counted."

In modern days, chimneysweeps' cancer has, of course, come to be regarded merely as a form of epithelioma, to which the irritating qualities of soot and the uncleanly habits of chimney-sweeps afforded predisposing local conditions. With increase of popular habits of cleanliness and the extensive employment of mechanical devices for sweeping chimneys, the disease has practically disappeared. Only sporadic cases now occur, usually without determinable cause of local irritation. The history of the disease, however, presents a curious and interesting chapter of medical literature.

I have collected, abstracted, and arranged chronologically, without attempt to enumerate, a series of illustrative cases that have been reported for the most part by English authors. In instances in which the original article was not accessible for verification, I have merely quoted the reference without comment.

CHRONOLOGIC SERIES OF CASES FROM LITERATURE.

1731. *Bassius:* Obs. anat., 8°, Halae Magdeb., 193–197. Scrotum sphacelo consumtum et renatum.

1740. *Treyling:* Acta Acad. nat. curios., Norimb., v, 440. Scrotum immaniter auctum scirrhoso-scrophuloso.

1790. *James Earle:* Chirurgical Works of Percivall Pott, iii, 258.

In a footnote to the article on cancer of the scrotum in his first edition of Pott's works, he says:

"Since Mr. Pott published this tract, I saw the disease which is described in an infant under eight years of age who was brought into St. Bartholomew's Hospital and was an apprentice to a chimneysweeper. I shewed it to Mr. Pott, who acknowledged it to be the true disease, and that he had not before seen it in so young a subject. It had infected all the lower part of the scrotum, but as the testes had not imbibed the poison, the diseased part being removed, the wound healed and the boy was discharged perfectly well."

Of course, in the absence of microscopic verification, this case lies under strong suspicion of being, not carcinoma, but more probably some form of phlegmon.

1808. *Sir James Earle:* Ed. Chir. Works of P. Pott, p. 182.

A gardener of forty-nine who for five years had had "a large cancerous sore, which reached from the bend of the wrist to the knuckles, occupying almost the whole of the back of the left hand," and which first appeared while he was employed "to strew soot on the ground round the young and tender plants, to preserve them from the slugs. . . . He carried the soot in an old garden pot, which hung on his left hand by a handle over the top, while he strewed it with the right. . . . It is to be remarked that the right hand which strewed the soot was unaffected. Probably from that action it got rid of the effluvia, but the left, being . . . exposed to the vapors or dust arising from the soot, as it was continually stirred up, a lodgment of it was probably made on the thin skin at the back of the hand."

No treatment was of any avail till the patient consented to amputation, which was apparently curative.

1821. *Travers:* Med.-Chir. Trans. (1832), xvii, 346.

A chimneysweep of forty-three, who for three years had had on the scrotum a pimple, which finally became excoriated and ulcerated. The disease was twice removed, but recurred and the patient "died exhausted after some months of severe suffering. His emaciation was extreme. It was remarkable that the testicles, though exposed and shrunk, were not affected by ulceration; on inspection, the entire peritoneal surface was found studded with the small white tubercle of scrofula."

1824. *Henry Earle:* Med.-Chir. Trans., xii, 302.

A chimneysweep of thirty, who for seven years had had on his scrotum a wart which finally began to ulcerate and fungate. He was treated for a time by local applications, but finally submitted to operation, "at which time there was a large fungous excrescence, with hard thickened edges, which nearly covered the whole scrotum, and extended the entire length of the perineum to the verge of the anus. This discharged a profuse, bloody sanies, which excoriated the surrounding skin." The testes were not involved; the glands were enlarged, but later subsided, the patient was discharged well, quitted his occupation and stated that he had "no diminution in his venereal powers."

Page 304: A chimneysweep of thirty-five, who for a year had had a wart on the scrotum, which finally began to ulcerate and involve the right testicle. On admission to the hospital "there was a large deep ulcer extending into the body of the right testis, round which there was a considerable hard fungous growth from the edges of the skin, occupying about one half of the scrotum. This was excised, but recurred twice and was finally fatal. His grandfather, father and one brother had died of the same disease."

1825. *Warren:* Surgical Observations on Tumors, p. 329.

A patient of thirty-five, who six months before first noticed a wart on the scrotum. This became crusted and soon formed an open sore, which, when seen, was oval and the size of a half-dollar. The growth was excised, and the patient was without recurrence in 1848, thirteen years after.

1825. *Jeffreys:* The Lancet, viii, 318.

A chimneysweep of twenty-eight, who for ten years had had a wart on the scrotum. A year before admission, this wart began to ulcerate and to increase in size till it occupied the entire left side of the scrotum and angle of the groin, the left testis being exposed. The patient had a hemorrhage of about a pint from the tumor, which was treated with carrot and linseed meal poultices.

1835. *Syme:* Edinb. Med. and Surg. Jour., xliv, 13.

A chimneysweep of thirty, who two years before had a wart of the scrotum excised. Others soon appeared, and on admission almost covered the scrotum, which was completely removed, with recovery.

1837. *Samuel Cooper:* Dictionary of Practical Surgery, London, 1872.

A chimneysweep of twenty-three, married, had for five years had a small pimple or wart on the anterior part of the scrotum. The growth enlarged slowly, became indurated and two years ago began to ulcerate. On admission he presented "a large irregular ulcer at the lower and anterior part of the scrotum, with elevated, hard and red margins, which were in some parts very thick. The center of it was occupied by a foul adherent greenish slough. The disease did not involve the testes, and was completely excised. The glands were enlarged, but were not removed. The wound healed by granulation, and the patient was discharged well. Subsequent history unknown."

Lane, the editor, adds: "In the present day, the chimneysweeper's cancer is considered by most surgeons in every respect analogous to epithelioma in other parts."

1838. *Hawkins:* Lond. Med. Gaz., vol. xxi, p. 842.

An aged chimneysweep who for forty years had had a cancerous process in the scrotum. He was thrice operated on and finally was in hospital at the same time as his son with the same disease. Even then, his inguinal glands were not involved.

1838. *Gerdy:* Arch. gén. de méd., Paris, 3. s., ii, 385–391. Kystes et tumeurs cancéreuses des bourses et du testicule.

1841. *Welsh:* Lancet, xli, 90.

A chimneysweep who for ten years had had a wart on the right side of the scrotum, which finally began to fungate and ulcerate, presenting on admission "one granular cauliflower excrescence, hard to the touch, and emitting a stinking grumous kind of pus, unaccompanied with any severe pain." The entire scrotum was removed and healed, but a wart reappeared in four months, and two years later the scrotum was again removed, the testes not being involved. The wound was healing well at time of report, but later details are wanting.

1847. *Critchett:* The Lancet, vol. viii, n. s., p. 172.

A chimneysweep of twenty, who for four years had had on the scrotum an ulcerating sore which had spread rapidly in the past year. One uncle died of the same disease. On admission the patient showed an irregularly ulcerated sore on the left side of the scrotum, yellowish, secreting a thin, ichorous, very fetid discharge; the margin was irregular, elevated and hard; the glands of both groins enlarged. The growth was excised, the glands subsided, and the man was well and without recurrence a year later.

1841. *Liston:* The Lancet, xl, 793.

A chimneysweep of twenty-four who two years before first noticed on the left side of the scrotum a wart, which slowly increased in size. Five weeks before admission it ulcerated and began to discharge. The tumor was excised and the enlarged, indurated inguinal glands dissected out. The wounds healed after suppuration, and the patient was discharged well.

Another chimneysweep of thirty-four, who had three small ulcerating scrotal warts removed.

1849. *Cooper, Bransby:* London Med. Gaz., xliii, 5.

Reports seven cases, all in chimneysweeps aged fifty-one, thirty-four, thirty-one, twenty-eight, thirty-six, thirty-five, sixty-six.

1849. *Bird:* Prov. Med. and Surg. Jour., 127–129.

Curling: London Jour. Med., i, 220–223.

Hutton: Proc. Path. Soc. Dubl., i, pt. ii, 66–70.

O'Ferrall: Proc. Path. Soc. Dubl., i, pt. i, 297–305.

1852. *Stanley:* Med. Times and Gaz., v, 414.

A chimneysweep of forty, whose father had followed the same trade, and who for nineteen years had had a cancerous process in the scrotum, thrice operated on and thrice recurrent, the last time in the inguinal glands, which were removed with apparent cure.

1855. *Stanley:* Med. Circ., London, vii, 202.

Chimneysweeper's cancer and cancer of the penis.

1859. *Stanley:* The Lancet, London, xxxi, n. s., 612.

A chimneysweep of about thirty-five, with two ulcerated tumors on the right side of the scrotum, near the most dependent portion. The glands were not involved. The tumors were excised. Stanley alludes to cancer of the scrotum as "this well-known although now less common disease, which . . . occasionally presents itself for treatment at our hospitals."

1863. *Coote:* The Lancet, London, xl, 420.

A chimneysweep of thirty, who eight years before had had a small wart removed by Stanley (see reference above), had a recurrence four years ago. The growth is now an ulcerated mass involving the entire scrotum and the base of the penis. Growth excised; healing good.

An elderly chimneysweep, in whom the left testis was involved and the glands enlarged, and only partial removal done by Mr. Holmes.

1864. *Stevens:* The Lancet, xlii, n. s., 570.

A chimneysweep of forty-six, "with carcinomatous ulceration of the entire anterior surface of the scrotum of eight months' duration, involving the penis and having destroyed nearly half its structure." Treated by complete removal of the genitalia.

1865. *Putéquat:* Bull. Soc. de chir. de Par., 2. s., vi, 474–477. "Observation de cancer des ramoneurs ou du scrotum."

A gentleman of fifty-five, not a chimneysweep, who had a chancre ten years before, developed on the left side of the scrotum a large, irregular ulcer, with a grayish aspect, uneven surface, thick, hard, elevated, broken and everted borders. Left testis involved but glands not enlarged. The patient, unoperated, died in a year. Putéquat remarks that "cancer of the scrotum is very rare in France," and quotes Samuel Cooper as saying in his "Elementary Treatise of Surgical Pathology," p. 622: "Le cancer du ramoneur est une maladie pernicieuse sur laquelle les médicaments internes et les topiques ont une action faible ou nulle.

Idem: J. de méd., chir. et pharmacol., Brux., xli, 509–512. *Idem:* Gaz. d'hôp., Paris, xxxviii, 546.

1866. *Curling:* A Practical Treatise on Diseases of the Testis and of the Spermatic Cord and Scrotum, p. 599.

A chimneysweep of fifty-one, who began the trade at seven, and who for twenty-two years had had a cancer of the scrotum, operated on five times and ultimately causing death from emaciation, with only one groin involved and no trace of internal metastasis.

Cusack: Dubl. Jour. Med. Sci., xxi, 137.

Reports excision of a soot-wart from the hand of a female chimneysweep, whose son had a similar epithelioma of the ear.

1865. *Sauné:* Bull. Soc. anat. de Paris, xl, 636. Cancroide du scrotum.

1868. *Rouge:* Bull. Soc. méd. de la Suisse Rom., Lausanne, ii, 315. Cancer mélanique du scrotum.

1868. *Lawson:* Brit. Med. Jour., London, i, 351.

1869. *Erichsen:* Brit. Med. Jour., London, i, 211.

A chimneysweep of forty-nine, who six months before admission received on the scrotum an abrasion, at the site of which developed a purple scab, followed by a rapidly spreading red growth, which became black and painful. On entrance there was presented a raised and rather pigmented ulcerating growth on the scrotum, which was excised and healed perfectly. Further history unknown.

1874. *Bell:* Edinb. Med. Jour. (1876–7), xxii, 135–137.

A paraffin worker of forty-seven who for five years had had extensive but painless ulceration of the scrotum, with elevated exuberant granulations. He had had several operations followed by recurrence. Glands not enlarged. The mass was widely excised and the wound healed. Further history unknown.

1875. *Gerdy:* Mélanges d'anatomie, 8°, Paris, ii, 450–456.

1875. *Bell.*

A paraffin worker of thirty-four who two years before noticed on the scrotum a small pimple which has grown to a tumor three inches in diameter, involving the right tunica vaginalis and the skin, and yielding a thin discharge. Glands in both groins enlarged but not hard. Mass excised. Wound healed. Subsequent history unknown.

Both these patients had paraffin acne or eczema over those parts of hands, arms and legs not protected by clothing. This is described by Ogston: Edinb. Med. Jour., xvii, 544.

1875. *Gerdy:* Mélanges d'anatomie, Paris, ii, 450–456.

1879. *Cameron:* Glasgow Med. Jour., 5. s., xii, 40.

1883. *Heath:* The Lancet, 1883, ii, 327.

A block-cutter of eighteen, who a year before first noticed a small hard swelling, the size of a marble, in the right lower scrotum. In three months it grew to the size of a hen's egg; four months later the glands in both groins began to enlarge (the right first). No pain till three months ago. On admission, the growth involved the whole scrotum, irregular, nodulated, with a sinus at the bottom, from which was discharged a thin, yellowish, opaque fluid, sometimes tinged with blood. Death followed in four months from hemorrhage. The testes were uninvolved. Pathological report: Epithelioma.

1888. *Wilson:* Prov. Med. Jour., Leicester, vii, 69.

1889. *Butlin:* St. Barth. Hosp. Rep., xxv, 193–200.

During the past twenty-five years, seven cases have been entered in the records of the Massachusetts General Hospital under the diagnosis of cancer of the scrotum. Of these, one was secondary to cancer of the penis; and two, though undoubtedly cancer, were not verified by microscopic examination.[1] There remain, therefore, four cases of unquestionable primary cancer of the scrotum. The history of these four patients I shall report

[1] All three of these cases have since died with a clinical diagnosis of cancer.

in brief, as a contribution to the case-literature of the subject. For the privilege of making this report I am indebted to the courtesy of those members of the staff of the Massachusetts General Hospital in whose services the cases occurred. I wish to present my grateful acknowledgments to them and to the administrative officials of the hospital who have permitted and facilitated my use of the records. I wish also to thank Mr. Aitken and Mr. Brown for their interest and assistance in preparing the three cuts with which the cases are illustrated.

Case I. M. C., sixty, male, West Surgical, 229–90. Born in Ireland. Laborer. Entered Jan. 10, 1887. For three months patient had had a painful, indurated ulceration on the right scrotum, the size of a half-dollar, which he attributed to scratching. At operation, by the late Dr. C. B. Porter, the mass of tissue underlying the ulcer was removed without opening the tunica vaginalis. The glands in the groin were dissected. Pathologic report by Dr. W. F. Whitney: Epithelioma. After operation the patient had a slight bilateral hydrocele, which, however, soon disappeared, and he was discharged relieved on Feb. 3, 1887. I have been entirely unable to trace his subsequent history.

Case II. T. S., forty-nine, male, East Surgical, 396–102. Born in England. Mule-spinner. Entered Oct. 16, 1901. Six years previously patient had received in the posterior aspect of the left scrotum a wound with a pick, from which had gradually developed a painless ulcer two inches in diameter and not particularly indurated. At operation, by Dr. J. C. Warren, the ulcer was excised with part of the tunica vaginalis, and the glands of the groin dissected. Pathologic report by Dr. Whitney: Epithelioma. The patient was discharged relieved on Oct. 29, 1901, and on June 13, 1908, reported himself by letter as well and entirely free from local recurrence, though he says he has had for years on the calf of his left leg a similar growth which causes him no inconvenience.

Case III. J. O., sixty, male, East Surgical, 458–35, 518–245. Born in England. Spinner. Entered Oct. 3, 1903. A year previously the patient had been tapped for hydrocele, and at the site of puncture had developed a soft, painful, ulcerated, toodstool-like mass, the size of a silver dollar, to the left of the median rhaphé of the scrotum. At operation by Dr. J. C. Warren the tumor was excised and a radical cure of the hydrocele performed. Pathologic report by Dr. Whitney: Epithelioma. The patient was discharged much relieved on Oct. 26, 1904. On Sept. 1, 1905, he was readmitted for recurrence in the glands of the left groin of six weeks' duration. A mass the size of a plum was excised from this groin by Dr. R. B. Greenough, and the patient again discharged on Sept. 28, 1905. He died, however, on Nov. 17, 1905, with scrotal recurrence associated with profound anemia.

Case IV. M. J. F., sixty-four, male, East Surgical, 594–137. Born in Ireland. Currier. Entered Dec. 26, 1907. Four months previously, the patient had been operated for varicocele, and at the scar of incision had developed a hard, ulcerated, painful mass, the size of a horsechestnut, in the left lower anterior aspect of the scrotum. (Fig. 1.) At operation by Dr. F. B. Harrington the tumor was excised without opening the tunica vaginalis, and the glands of both groins were completely dissected. Pathologic report by Dr. Whitney: Epithelioma, glands not malignant.. The patient was discharged on Jan. 1, 1908, and has not since been heard from. Fig. 2 illustrates the microscopic appearance of the tumor. Fig. 3 is a drawing of a specimen in the Warren Museum, from a similar case, which I am permitted to reproduce by the courtesy of Dr. Whitney, to whom I wish to express my sincere thanks for this and for the use of his pathologic reports.

These cases are, of course, too few, and their ultimate history too imperfectly known, to warrant any statistical study or inferences. They are presented merely to place them on record. It is interesting to note that all the patients were born in the British Isles and that two of them were spinners, though it is doubtful if these facts are of any etiologic significance. More important is the fact that in three cases there was a definite history of precedent trauma. Only accumulation of more extensive data would, however, justify conclusions on the subject. At present it seems that cancer of the scrotum, in its early stage at least, is one of the forms of superficial epithelioma to which radium treatment would be particularly suitable.

THE TECHNIC OF ARTHROTOMY. A REPORT UPON AND DISCUSSION OF ONE HUNDRED AND NINETY-EIGHT CASES.

BY CHARLES P. PAINTER, M.D., AND ANDREW P. CORNWALL, M.D., BOSTON, MASS.

(From the Orthopedic Clinic of the Carney Hospital.)

[Concluded from No. 20, p. 764.]

ARTHROTOMY OF THE HIP-JOINT. INTRACAPSULAR FRACTURES. EXCISIONS. ERASIONS.

Case 164. M. D., female, thirteen, single. Separation of upper femoral epiphysis. Operation, May 12, 1903.

Incision 12 cm. in length over the anterior aspect of the left hip-joint. On separation of soft tissues the capsule was found intact. No evidence of disease. When opened fracture found to be transverse directly between the juncture of the head and neck. Cartilage clear and smooth. Head vascular and cotyloid ligament small. Shaft of femur rotated out and the whole drawn up by traction so that it was impossible to approximate ebony surfaces, so the periosteum was removed from the shaft of bone below greatest prominence of tuberosity and the head was fixed to this surface with silver wire.

Leg held in complete extension with splint and traction.

June 2. First intention. Apparently good union. Plaster spica applied.

Leg in good position with slight amount of adduction.

June 16. Discharged.

Case 165. C. T., female, fifty-one. Intracapsular fracture neck of right femur. Operation, June 27, 1906.

U-shaped incision employed. Fracture found with fibrous tissue interposed between fragments. The latter was removed and fragments approximated. Two nails

were driven into femur through great trochanter and neck into the head of the bone. Capsule then sutured. Long T-side splint used to hold leg in position. Later a plaster spica was applied.

Aug. 21. Cast removed, fracture apparently united.

Sept. 1. Flannel spica reinforced with felt.

Sept. 14. Walking with crutches.

Sept. 30. Discharged. Relieved.

CASE 166. J. H., female, twelve, single. Congenital dislocation of hip. Operation, Nov. 11, 1901.

Linear incision 6 in. long over trochanter at central point. Neck of femur found in position of extreme coxa vara combined with a backward twist of the neck. There was an entire absence of femoral head. The neck did not measure over ¾ inch in length. To expose the neck in its abnormal position it was necessary to remove the insertion of the gluteus medius. Neck of bone then removed. Free end of muscle sewed back upon trochanter with silk and fibrous capsule of joint closed.

Dec. 1. Discharged.

CASE 167. J. S., female, twenty-three, single. Congenital dislocation left hip. Operation, May 1, 1907.

Anterior incision used. Head of femur found back on dorsum of ilium. Acetabulum very shallow. Capsule infolded about the head so that it could not be approximated to the acetabulum. In addition, the adductor muscles were myotomized and after enlarging the acetabulum the head was replaced and wound closed. Plaster spica applied with forcible extension and abduction.

May 15. Slight sepsis intervened which has yielded to treatment.

May 22. New spica applied.

June 4. Patient walking on crutches. Wound clean. Discharged home.

January, 1910. Patient walks without artificial support of any kind, and there is scarcely any limp, so well is the shortening accommodated for by an extension boot.

CASE 168. L. W. McP., male, twenty, married. Intercapsular fracture. Operation, March 26, 1909.

Anterior incision, neck of femur exposed. No line of fracture could be made out, but head much lower than normal with relation to trochanter. Capsule opened and wedge-shaped piece of bone removed from neck just behind the epiphysis. Wound closed. Long plaster splint with leg in abduction and internal rotation.

April 21. Spica changed.

May 2. Discharged with spica.

June 23. Readmission. Since discharge has worn spica. X-ray shows marked coxa vara, but apparently firm bony union has taken place. One-inch shortening and very little motion.

June 26. Discharged. Instructed as to exercises. Flannel spica.

CASE 169. D. F., male, forty-three, single. Old fracture internal condyle, knee. Operation, June 29, 1906.

Semilunar incision over inner aspect of left knee. Capsule adherent, so incision was continued as for excision of the joint. Internal condyle fractured, but adherent by fibro-osseous tissue. This tissue was removed and fragments apposed by three silver wire sutures. Periosteum brought over fracture line as far as possible and tied with kangaroo tendon sutures. It was impossible, however, to completely extend the leg or correct the deformity. Wound closed. Posterior wire splint.

Aug. 17. Plaster cast applied.

Aug. 22. Discharged wearing cast. Conditions gradually improved, but deformity remained partially uncorrected.

CASE 170. R. D., male, forty, single. Spur on head of tibia. Bursa over head of fibula. Operation, Feb. 1, 1907.

Bursa dissected out *en masse*. Capsule of knee-joint opened and spur found projecting upwards towards fibula from tibial head. This was removed. No other abnormalities found.

Feb. 10. Discharged. Complete recovery.

CASE 171. J. S., male, thirty-three, married. Intracapsular fracture, right hip. Operation, July 12, 1901.

Incision over anterior surface of the right hip-joint. When the capsule was opened, the fracture was found at the junction of the head and neck. Head of bone displaced downward and forward, but still firmly attached to the acetabulum. The head of the bone was excised in pieces and wound closed. Extension side splint used to hold leg in abducted position.

July 31. Splint removed. Free motion in the joint, but considerable induration about the incision and a small discharging sinus. This healed up promptly and patient has fairly good functional result.

CASE 172. J. T., male, thirty-four, single. Operation, Jan. 14, 1903.

A T-shaped incision was made over the lateral aspect of the left femur just over the trochanter. Neck of the femur exposed, capsule opened and fracture found with an interposition of fibrous tissue between the fragments which caused permanent adduction and instability. This tissue was excised and bony surfaces curetted, then approximated and impacted with leg in abduction. Wound closed. Plaster cast applied to retain abduction with slight flexion.

Feb. 7. Discharged. Recovery uneventful.

June 19, 1903. Motion in flexion limited to within 10° of a right angle. Some permanent outward rotation. Inward rotation limited about one half; abduction restricted to about one third normal.

Left leg, 81.6 cm.; right leg, 83.5 cm. From umbilicus, right leg, 88; left leg, 86.5.

CASE 173. H. B., male, twenty-seven, single. Operation, Feb. 8, 1904.

Left hip-joint opened through incision over inner aspect. An oblique fracture was found partly intracapsular and partly extracapsular. The fragments were not united, but presented a pseudarthrosis. A small amount of redundant cartilage which was interposed between the fragments was trimmed away. The surfaces of the apposing fragments were then curetted. Head found fairly movable. Fragments approximated and a steel wire nail driven through trochanteric fragment, and into the head of the femur. Small wick inserted and wound closed. Leg put up with plaster spica in abduction and slight internal rotation.

Feb. 26. New spica. Union by first intention.

April 8. Discharged, using crutches.

CASE 174. B. McD., male, fifty-eight, married. Operation, Aug. 12, 1904.

Anterior incision used. Old ununited fracture found. The head and fragments of upper part of neck were removed. The remaining upper surface of bone curetted and allowed to drop in towards the smooth acetabulum. Wound closed.

Sept. 16. A few degrees of motion obtained under ether. Gauze spica applied.

Oct. 4. Plaster spica.

Oct. 7. Discharged.

CASE 175. R. D., male, fifteen, single. Operation, April 5, 1907.

Anterior incision used over right hip. It was impossible to bring opposing fractured surfaces in proper relation for wiring, in addition to which the head of

bone was very friable and in three pieces. The latter were removed and capsule closed. Spica applied in extension and abduction.

April 25. Discharged. Convalescence uneventful.

April 9, 1908. Re-entered hospital.

Arthroplasty was advised, in attempt to attain motion. This operation was performed on following day and extension applied.

May 1. Passive movement shows that motion is present, but causes considerable pain.

May 12. Movement of joint increasing. Discharged.

Case 176. W. McM., male, thirteen, single. Operation, May 28, 1908.

X-ray shows separation of head from neck at about epiphyseal line. Attempt was made to manipulate leg in order to obtain union without incision. Leg was put up in plaster spica with leg and thigh strongly abducted.

June 16. Discharged, wearing spica.

March 15, 1909. Re-entered hospital.

Patient wore plaster spica for about four months and flannel spica since that time.

Left leg in marked outward rotation, complete extension and slight adduction. Few degrees of motion. No abduction. Trochanter, ¾ in. above Nélation's line, 1½ in. shortening with some atrophy of thigh and calf.

March 17, 1909. Operation.

Anterior incision used. Capsule incised revealing very short neck with marked coxa vara, with line of fracture found impacted just behind epiphyseal line. Little displacement. A wedge-shaped piece of bone removed from neck which permitted abduction without force. This brought the neck in perfect apposition with the head. Wound closed. Long plaster spica, including foot, applied.

April 20. Discharged wearing cast.

Case 177. S. A., male, sixteen, single. Operation, Aug. 24, 1908.

Anterior incision used and right hip-joint opened. Head apparently normal. Fracture at epiphyseal line. Opposing surfaces were freshened and after a myotomy of the adductors had been performed the fractured ends were sutured together with silver wire. Wound closed and spica applied with leg in abducted position.

Oct. 9. Discharged home wearing spica.

Dec. 21, 1908. Re-entered hospital.

Patient about on crutches and cane. No pain. Still has 1 in. shortening of leg. Patient put in bed and extension applied for one week.

Jan. 9, 1909. Operation.

Incision parallel to old scar. Silver wire removed from head and neck of bone. Apposing bony surfaces which were not in apposition or united were again freshened. Leg then forcibly pulled downward with slight internal rotation. A wire spike was then driven from outer side of thigh passing through trochanter and neck into head of bone. Leg then put up in plaster spica.

Feb. 10. Spica reapplied. About 2 inches shortening indicates that spica was not sufficient to hold softened bone in position.

Feb. 21. Discharged home wearing spica.

Case 178. L. F. B., female, twelve, single. Permanent flexion with restriction of motion at left elbow following recent fracture of external condyle. Operation, April 29, 1904.

Incision 6 cm. parallel with long axis of arm with center opposite inner aspect of left inner condyle. Muscles separated by blunt dissection, which was continued along flexor surface of coracoid process. All structures then retracted upward. Similar incision made on outer side over external condyle, condyle directed inward and forward as arm was supinated, due to repair of fracture in faulty position. A slice 1 cm. in thickness was removed from the most prominent portion of external condyle on flexor aspect. This permitted a slight increase in flexion, which was measured to 45° beyond a right angle by removal of callus between this and posterior quarter of radial head. Motion not perfectly free, however. Capsule repaired and wound closed, arm secured with adhesive plaster in position of greatest possible flexion.

April 30. No pain, but two outer fingers are numb. Some few degrees in flexion lost.

May 6. Stitches removed, wound healed. Motion in flexion same as during operation. No gain in extension. No forced motion attempted, however.

Discharged home.

Ultimately she secured good function in the arm.

Case 179. A. S., male, fourteen, single. Tubercular hip. Erasion of hip-joint. Operation, Oct. 28, 1901. Usual hip incision made and head of femur exposed. Granulation tissue which filled the fossa was removed. A considerable amount of carious bone was found upon the posterior surface of the neck of the femur, — a lesser necrotic area was found opposite this point on the acetabular rim. Both areas were removed and bony surfaces remaining curetted. Tincture of iodine applied and wound closed. Light traction applied to the leg with sand bags to prevent eversion.

Nov. 27. Discharged, wearing spica.

Further history cannot be obtained.

Case 180. W. K., male, twenty-four, single. Excision of head of femur. Operation May 7, 1902.

Linear incision over right trochanter. Neck of bone practically destroyed. The remaining portion was removed close to the trochanter, cartilage over head of bone lifted off and granulation tissue found underneath. Cotyloid ligament partially destroyed. There was but slight evidence of acetabular disease, but the cavity was curetted and tincture of iodine applied. Wound washed, and closed with provisional sutures.

June 5. Patient has had septic temperature from the second day after the operation. Discharge from wound, which has been profuse, is diminishing in amount. A fluctuating area has appeared in the groin. When incised a large amount of greenish pus was evacuated.

Aug. 9. Patient has steadily grown worse. Again has a profuse discharge and intense pain. Discharged.

No further history can be obtained.

Case 181. I. T., male, thirty-six, single. Arthrotomy. Operation, June 25, 1902.

Large semilunar incision over great trochanter of right femur. The neck of the bone was exposed and found covered with bony spicules. The rim of the acetabulum was thickened and head of the bone presented a mushroom appearance. No motion in the joint. The head and a portion of the neck and a spur on the acetabulum were removed, the former in pieces. No evidence of acute bone disease present. The trochanter was allowed to drop in towards the acetabulum and the divided muscles sutured to capsule after thorough irrigation. Wound closed leaving wick and one provisional suture. Leg put up in abduction with slight traction.

July 7. Measured for hip splint. Slight serous discharge persists since removal of wick.

Aug. 2. Discharged relieved.

Dec. 19. Patient walks about five or six miles a day. Motion in flexion to 45°, abduction limited. No trace of active disease can be found.

Case 182. T. O'L., male, seventeen, single. Erasion of hip-joint. Operation, July 16, 1902.

Incision 10 cm. over great trochanter of left femur. Capsule found much thickened by tubercular granu-

lation tissue. No evidence of bone disease seen in that portion of the head, and neck exposed. The region about the head and acetabulum curetted and a small portion of the capsule excised. Wound closed and plaster spica applied with leg in slight flexion.

July 22. Patient has had intense pain in the hip and leg since operation.

Aug. 1. General condition poor and getting progressively worse. Wound healed, but lung shows acute tuberculosis.

Aug. 4. Patient died three days after onset of acute peritonitis. No autopsy obtained.

CASE 183. A. N., male, fifty-five, married. Osteoarthritis. Arthrotomy of hip-joint. Operation, Oct. 8, 1902.

Anterior linear incision used. Head and neck of the bone exposed and the femur was found to be firmly ankylosed. Large spurs projected from the posterior rim of the acetabulum. The entire head of the bone was excised and the bony exostoses directly beneath. A large osteophyte 2 by 3 cm. removed. Wound closed with drainage.

Oct. 20. Spica applied under anesthesia, to overcome muscular spasm. External rotation corrected about 20°.

Nov. 16. Plaster cast reapplied. Less tendency to external rotation than at any time since operation. Patient walks about with crutches and can bear some weight upon the affected leg without pain. Discharged.

Dec. 17. Patient has about 15° of motion in flexion and abduction.

CASE 184. D. L. S., male, forty-seven, married. Excision of head of femur. Operation, Oct. 29, 1902.

Anterior incision utilized to open the right hip-joint. Capsule much thickened. Neck of bone separated from adjoining tissues as much as possible and posterior surface found much eroded. The head and neck of the bone were removed. Acetabulum not involved, but showed a slight roughening on its lower, inner aspect.

Wound irrigated and tincture of iodine applied. Posterior opening for drainage. Two wicks left for this purpose and wound closed.

Nov. 5. Patient has now a mild septic temperature. Wound broke down to-day and about 50 ccm. purulent fluid escaped.

Dec. 30. Wound has been dressed daily. One sinus has healed. Discharge diminishing in amount. Patient is about on crutches with crutch splint applied.

Jan. 10. Discharged.

CASE 185. E. G., female, fifteen, single. Tuberculosis head and neck right femur. Erasion. Operation, Nov. 27, 1903.

Longitudinal incision 11 cm. long with middle opposite and posterior to neck of femur.

Capsule was grayish, edematous and contained a small amount of turbid fluid. Cartilage over head of femur thin and readily stripped off. The diseased bone extending 1.5 cm. along upper surface of neck adjoining head, comprising upper and posterior quadrant of head, was curetted out down to hard bone.

Diseased synovial fringes removed as far as possible. Acetabulum not seen, but felt to be smooth and was not disturbed. Tincture of iodine applied and wound closed leaving drain. Extension with 6 lb. weight.

Dec. 21. Few degrees of motion at hip in all directions without pain.

Dec. 23. Plaster spica applied.

Jan. 18, 1904. Discharged.

Re-entered hospital July 9, 1905.

Has psoas abscess and discharging sinus from hip. The abscess was incised and drained.

July 27. Discharged improved.

CASE 186. M. M., female, twenty-one. Tuberculosis of right hip. Excision. Operation, Dec. 1, 1909.

Incision over outer side of hip. When capsule was opened an abundance of granulation tissue was found. Trochanteric portion of neck entirely "eaten away," the head being in contact with trochanter. Capsule smooth, but head of bone rough and eroded.

Head of bone excised and sequestrum removed.

Capsule closed with catgut. Wick inserted and wound closed.

Dec. 2. About 3 lb. extension applied. Wound healed by first intention. Joint still sensitive but much less so.

Dec. 29. Plaster cast applied. Model made for leather spica.

CASE 187. C. T., male, twenty-five, single. Tuberculous elbow. Arthrotomy. Operation, June 25, 1909.

Linear incision to outer side of olecranon and joint opened. Tubercular granulations protruded from the wound. Pannus over joint surface, which was removed as far as possible.

Wound closed and plaster cast applied with arm at right angle.

CASE 188. P. M., male, twenty-six, single. Tuberculous shoulder. Excision. Operation, Jan. 16, 1909.

Five-inch incision over anterior surface of joint. Muscles separated and capsule exposed. Adhesions broken up by manipulation and some motion secured. Cartilage of head and glenoid cavity much eroded. Head of bone atrophied. Most of this removed, together with the upper portion of greater tuberosity, to allow abduction, which was impossible owing to upward displacement. Capsule turned into joint and sutured, as it was not possible to get any fascia. Shoulder spica, arm abducted 60°.

June 13. Spica removed.

June 16. Passive motion.

June 25. Ether manipulation, 25° abduction, few degrees of rotation. All motions were forcibly increased.

June 29. Discharged.

CASE 189. G. A., male, twenty-three, single. Tuberculosis left hip. Excision. Operation, Oct. 17, 1906.

Incision over outer surface of left hip. Capsule opened and a slight amount of pus evacuated. A Gigli saw passed around neck of femur and head of bone excised. Latter showed extensive disease. Acetabulum not involved. Tincture of iodine applied, capsule and wound closed, leaving wick. Traction applied.

Dec. 22. Patient has now a septic temperature. Treatment by tuberculin and pyocyaneus vaccine and local dressing with chlorate of soda. Marked improvement past three weeks.

Jan. 16. Spica applied, under ether, to insure good position of leg.

Jan. 27. Discharged.

CASE 190. G. R., male, seventeen, single. Tuberculosis of hip. Arthrotomy. Operation, Dec. 31, 1909.

A four-inch incision made over outer surface of upper thigh. Head of femur exposed and found dislocated upwards and backwards. Scar tissue in considerable amount dissected away from about head of femur. Latter freed and leg adducted. An acetabulum made, as it was not possible to utilize the old one owing to its shallowness, and the muscular contractions preventing the replacement of the head. Leg then forcibly abducted and rotated inward with traction applied at the same time. Wound closed and plaster spica, foot to chest, applied with leg in above-mentioned position.

Jan. 3, 1910. Patient complains only of the upper part of cast.

Should operation be successful, i. e., ankylosis obtained, an osteotomy is to be performed later.

Case 191. J. C., male, thirty, single. Tubercular wrist. Excision. Operation.

Long linear incision over dorsum of hand. Capsule found thickened and lined with tubercular granulations. All of the carpal bones involved and were removed. Surrounding area cleaned up as much as possible and tincture of iodine applied. Wound closed and anterior splint applied.

Aug. 31. Discharged.

June 1, 1905. Patient re-entered hospital. Condition of hand has steadily been growing worse. General health poor. Hand was amputated two inches above the radio-carpal articulation.

Case 192. E. H., male, nineteen, single. Infectious arthritis hip. Erasion. Operation, Feb. 10, 1906.

Incision made over right trochanter; joint opened. Head of bone covered with granulation tissue, which was removed and wound closed.

March 9. Patient has a great amount of pain in both hips and knees. Considerable deformity in adduction and flexion with a very few degrees of motion in rotation.

March 16. Right hip-joint opened through scar of previous operation. Capsule opened and head of femur rotated out of acetabulum. It was found to be the site of considerable inflammatory tissue, and it was thought advisable to excise the head and a small portion of the upper part of the neck. Wound then closed, after irrigation, and leg put up in extension.

May 17. Progressive improvement to date. Discharged.

Oct. 25. Right hip ankylosed at angle of 90°. No other deformity. Osteotomy performed and myotomy of tensor vaginæ femoris, ilio-femoral band and outer head of the quadriceps femoris. Wound closed and leg put up in extension on a T-splint.

Nov. 2. Fairly profuse greenish, purulent discharge.

Nov. 15. Pyocyaneus vaccine, 250,000,000.

Nov. 20. Discharge diminishing rapidly.

Nov. 21. Extension removed and plaster cast applied.

Dec. 3. Discharged. Walking on crutches. Leg in fair position.

Case 193. A. B., male, thirty-three, single. Arthrotomy hip. Operation, April 13, 1906.

U-shaped incision over right trochanter. When capsule was opened, a large spur was found projecting from rim of acetabulum downwards upon neck of femur. Spur removed and leg could now be abducted and hyperextended to almost normal limits. Wound closed.

April 27. Spica applied.

May 9. Discharged wearing light spica.

Case 194. M. B., female, sixteen, single. Spur on rim of acetabulum. Operation, June 22, 1906.

U-shaped incision over head of left femur. Capsule exposed and divided. Spur found on upper half of acetabular rim, projecting about ¼ inch. When this was removed it was possible to flex and abduct the leg to nearly normal amount.

July 6. Under anesthesia leg manipulated and put up in plaster in 40° flexion.

July 9. Discharged.

Case 195. B. B., male, thirty, married. Operation, Aug. 17, 1906.

On July 11, 1906, hip was manipulated under ether. Flexion obtained to 90°. Abduction 50°, and some rotation.

July 25. X-ray shows spur on upper rim of acetabulum. Left hip-joint opened, spur removed. Cartilage found eroded over articular surface of femur. An inflamed bursa found over great trochanter and removed. Joint irrigated and wound closed.

Aug. 30. Plaster spica applied under ether. Pathological examination of tissue removed at time of operation shows tuberculosis.

Sept. 13. Discharged.

Case 196. M. P., female, thirty, single. Tuberculosis of shoulder. Excision. Operation, Nov. 8, 1901.

Incision 5 inches long made parallel with outer margin of bicipital groove and ½ inch to its outer side. Capsule of joint exposed without cutting any muscle fibers. Head of bone, which was badly diseased, was removed just below tuberosity. The anterior inferior portion of the capsule was markedly thickened and covered with tubercular granulation tissue extending over to cover floor of glenoid cavity. When this pannus was removed cartilage was not found eroded. Tincture of iodine applied. Wick placed to bottom of wound and later closed with provisional sutures. Two silk sutures used to draw fibers of deltoid together.

Dec. 18. Voluntary motion 10°. Passive motion through nearly normal arc. No evidence of acute disease remaining.

Jan. 29, 1902. Can extend arm by climbing wall. With aid of other hand can raise hand to head.

March 5. Motion improving. No pain.

Oct. 24. Excellent result. Can carry food to mouth and comb hair. No recurrence of disease had taken place in 1906, and patient was doing the work for a large family and has fairly good motion.

Case 197. H. C., female, twenty, single. Tuberculosis of shoulder. Excision. Operation, April 26, 1907.

Incision 3 inches long made over internal aspect of humeral head and carried down to bone. Bone chiselled and pieces of soft friable bone found underneath. This was removed. Tincture of iodine applied. Cigarette wick and wound closed. Valpeau bandage.

April 29. Wound clean, wick removed. Patient out of bed.

May 8. Shoulder comfortable. Discharged home.

June 12. Ten degrees motion in shoulder-joint.

April 13, 1908. Pain in shoulder constant for past two weeks, worse at night. X-ray shows some articular destruction. Plaster cast applied to shoulder.

May 12, 1909. Re-entered hospital.

Incision made parallel and immediately to inner side of old scar. An abundance of scar tissue was encountered before reaching the capsule. The latter was thickened. When incised the head of the humerus was found eroded and was removed down to greater tuberosity. Glenoid cavity rough and was curetted. No active disease present here. The posterior portion of the capsule was brought over the excised head and sutured to the anterior portion of the capsule with chromic catgut in attempt to prevent ankylosis.

May 14. Drain removed, wound clean.

May 18. Stitches removed. Has had passive motion daily since last note.

May 25. Discharged home.

Case 198. B. W., female, forty-four. Ankylosis of shoulder, hypertrophic. Excision. Operation, Jan. 26, 1906.

Incision 7 cm. in length over greater tuberosity of right humerus. Capsule opened. Periosteum over tuberosity stripped off and soft bone found with evidence of an old ununited fracture. Head and tuberosity excised, all loose bone curetted out. Capsule then closed. Skin wound also closed and Valpeau bandage applied.

Feb. 2. Stitches removed.

Feb. 14. Shoulder much improved. Discharged.

In this group there were four cases of infection and one death. In the case of the patient who

died, the infection was not a wound infection, but was due to the lighting up of a pulmonary lesion and secondary acute tuberculosis, but it is included here because the patient died in the hospital within three weeks of the time of the operation upon his joint.

The other infections caused no permanent injury to the joints involved. In the different groups we have the following results: In Group 1 there were seven infected joints and one death; in Group 2, there were four infected joints and one death; in Group 3, there was one infected joint and that case died; and in Group 4 there were four infections, three of the joints, and one death, which, however, was an acute general tuberculous infection following the arthrotomy. Counting the deaths and infected joints altogether as infections, this gives a little over 8% of infections in the 198 patients operated. The mortality figures as a little over 2%.

There has been improvement in our results as time has gone on and the use of urotropine as a routine in arthrotomies is destined, we believe, to materially lessen the risks of infection. It is difficult to summarize the results of a series of arthrotomies performed for so many different conditions and where the results to be anticipated are of such a variable character.

In the main, however, the results which it was sought to secure seem to have been attained in the large majority of instances with measurable success and we feel that arthrotomies may be undertaken for the relief of any of the conditions discussed in this paper without undue risk and that sufficient benefit will accrue to justify the performance of the operation. The technic, however, is one that should be perfected to such a degree that the liabilities of infecting a joint are reduced to a minimum.

Medical Progress.

REPORT ON PROGRESS IN ORTHOPEDIC SURGERY.

BY F. H. BRADFORD, M.D.

BONE TRANSPLANTATION.

UNTIL recently, the statement of Ollier, presented in 1867, that bone covered with periosteum can, if transplanted, heal and can grow, was generally accepted. The bone, however, should be taken from the same animal. In 1894, Barth showed in his experiment that bone periosteum or medulla dies on transplantion; Marshall, however, found that in young animals parts of transplanted bone will remain. The subject has excited renewed attention since the remarkable case of Lexer (recorded in Report on Progress in Orthopedic Surgery in the JOURNAL a year ago). This surgeon transplanted successfully an entire knee-joint, which was removed from a freshly amputated limb. Most observers report that the bony part of the transplanted piece practically dies. Lexer and Frankenstein, however, find that transplanted bone is, in time, fully vascularized. Periosteum transplanted with or without bone is preserved and capable of producing new bone, and the medulla is partially preserved. The process of transformation of the old bone to new bone is not, however, well understood, as various observers give different findings.

Kausch examined microscopically a dead bone nine months after transplantation, and found all signs of living and organized bone, and although in a pathologic anatomical sense transplanted bone dies, living tissue finally develops in the place of the transplanted bone. Hoffman excised the cartilage of joints of dogs and placed periosteum taken from the tibia of the same animal and caused a remarkable transformation of the end of the bone in adaptation to the function of the joint. Various experiments have been made with regard to the bone-producing power of the periosteum, and the results which have been obtained appear to substantiate the view that the periosteum properly treated has an unusual power of vitality.

Transplantation of bone, if successfully performed, will prove of value not only in filling defects of the diaphysis, but also of the epiphysis, following carious destruction of the joints, restoring motion to stiff joints. Furthermore, in stiffening flail joints and in pseudarthrosis, Codivilla has utilized flaps of periosteum. Lexer, however, recommends bone plugs for faulty union of the femoral neck. A hole is drilled through the neck of the trochanter and a piece of bone covered with periosteum is inserted, and bone plugs have been used to stiffen joints instead of the former method of arthrodesis. This has been successful at the ankle when a bone peg has been driven through the os calcis into the tibia and the ankle-joint. In the knee-joint the procedure has been less successful.

Lengthening of the tibia of dogs of a centimeter and a quarter has been successfully accomplished by performing osteotomy and screwing bone screws between the fragments. Living bone freshly taken from the same individual and covered with periosteum is regarded as the best material for transplantation, but bone can be taken from freshly amputated limbs. One reporter, however, Kausch, uses bone from a collection of bones taken from freshly amputated legs and preserved in alcohol and ether. Russell boils the bones in gelatine solution. Drew has used bone from a lamb; Tomita, that from a rabbit and also from a calf. Lexer prefers bone without periosteum if the old periosteum can be preserved, because of the danger of too extensive proliferation of osteophytes.

The surgical world without exaggerated hopes may anticipate in due time the development of thoroughly practical new procedures presenting a surprising advance in the art of surgery.

INFANTILE PARALYSIS.

The attention which has been called to this affection in American medical literature since the epidemic which occurred in New York a few years ago has borne fruit in a number of articles on the

subject discussing the question of the prevalence and communicability of this affection, and describing various local epidemics with suggestions as to treatment. The excellent work of the Massachusetts State Board of Health, as shown in their recent reports, has called popular attention to the present knowledge of the subject, and the report of the Orthopedic Department of the Harvard Medical School, published in the BOSTON MEDICAL AND SURGICAL JOURNAL, gives a succinct statement of all that is at present known in regard to treatment. Of great scientific interest are the investigations at the Rockefeller Institute and the Harvard Medical School, as well as elsewhere, showing that the disease can by inoculation be given to monkeys and transmitted from monkey to monkey, thus clearly proving the existence of contagion. Beside the masterly work of Flexner and Lewis, Robertson, Chesley, Gay and Lucas have called attention to the more recent findings in the pathology of the affection and the condition of the spinal fluid both of human beings and monkeys with this affection. But as to the nature of the contagion or the method of transmission, little is at present known. The medical profession is not only eager with expectation, but a condition of exaggerated alarm may be said to exist. It cannot be said that the number of cases of poliomyelitis reported by the boards of health, compared with those from tuberculosis, scarlet or typhoid fever, justifies a strict quarantine as has been recommended. It is certainly a question, though often claimed, whether the disease is more frequent now than formerly, though there is no doubt that more cases of infantile paralysis are reported. It will be remembered that the increase in the number of cases of congenital dislocation of the hip in the hospital records following the advent of Professor Lorenz, if presented in a statistical form, could be used to prove the existence of an epidemic. Until more exact information as to the communicability of this disease has been obtained, the wisdom of a stringent quarantine is questionable. As far as our knowledge goes, although there are a number of comparatively small epidemics which have been reported, in the great majority of cases the disease appears to be sporadic, occurring in widely separated communities.

The exaggerated dread of an unknown contagion may be natural, but unless reason based upon known facts is brought to bear upon the subject, the public may fall into a state of mind resembling that agitated by the fear of malicious animal magnetism.

SPASTIC PARALYSIS. OPERATIVE TREATMENT.

Spiller, of Philadelphia, in 1905, advocated resection of the posterior roots for the relief of spasticity, and in 1908, Förster, of Breslau, reported five cases operated upon by Lietze by this method, and recently Frazier, of Philadelphia,[1] writes a résumé of the subject with a report of additional cases operated upon by him. He claims that it is established that section of the posterior roots relieves, in most instances, spasticity even of an extreme type and of long duration, whether of cerebral or spinal origin, in adults and children. Of the thirteen recorded cases, this was true in all but one. The operation is not without danger. Of the fifteen cases recorded, two died of shock.

Spasticity in the successful cases is relieved so that passive exercises do not meet with resistance, and annoying and distressing reflex associated movements and exaggerated reflexes disappear permanently though the reflexes are not lost. Voluntary motive was restored to a marked degree in seven cases. Manifestly the operation should be reserved for the cases of severe grade.

Complementary to this, the method of alcohol injections into the nerves controlling the muscles in a state of spasticity is of value and interest.

Cases where this has been done with success are reported in an important paper by Allison.[2] Permanent cures were made, and the method, being without danger, is recommended in cases not benefited by muscle training.

SCOLIOSIS.

The best method of treatment of scoliosis is a question which still challenges the medical profession. Much has already been learned, but many important factors in the problem remain to be investigated. How largely our schools enter into the problem, what the schoolteacher can do to aid in prevention and cure, how common spinal curvatures are in our schoolchildren, all are questions which need careful investigation.

An attempt at a thorough investigation of this subject has been made by Haglund in Stockholm.[3] A trained specialist of many years' experience, he attempted to determine the number of children with curves of the spine in a public school. His investigation consisted in an examination of 1,600 schoolchildren. The obstacles to the investigation consist in the difficulty of determining a definite fixed standard of pathological curves. His first desire was to learn the number of deformities of the osseous system, including knock-knee, bow-legs and deformities of the feet; but the author was forced by the magnitude of the task to limit himself to an inquiry as to curvatures of the spine. The pupils were at first carefully inspected and those who presented a noticeable deformity of the back and trunk were selected for a more detailed examination. The examiner was surprised at the number of deformities which were found on the first examination. The experience of many years as a specialist helped the examiner to set for himself a standard enabling him to decide what curves were negligible and what needed some form of special treatment. Slight curves were not considered.

From his examination, he found that, of 1,600 children of the school examined, 362 were remanded for special examination, — that is, that nearly a quarter of the school children were in a condition to justify or demand treatment; in

[1] Surg., Gynec. and Obstet., September, 1910, p. 251.

[2] Jour. Orthop. Surg., October, 1910.

[3] Zeitschr. für Orthop. Chir., xxv. Band.

other words, over 22%. The ages of these children ranged from six to fifteen, and the curves were almost equally divided between boys and girls. If the ages of these children were examined, it was found the largest per cent of curves among boys was at the age of fourteen, whereas the largest per cent in girls was at ages eleven to thirteen inclusive; of both sexes, the largest percentage was from twelve to thirteen. If the curves were divided into two classes, the severe and moderate, it was found that 344 belonged to the second class and 18 to the first class, — that is, to those where other treatment than simple general gymnastics is necessary. In Class one, the less severe type, the girls were slightly in excess, that is, 22 as compared to 21%. Of the severe type, the girls were slightly in the minority, though the number (18) was too small for a definite conclusion.

Again, dividing the curves into two classes according to character, — that is, the scoliotic or lateral curves, and the sagittal or antero-posterior curves, — he found that among boys 90 cases were antero-posterior round-shouldered or hollow-back type and 134 scoliotic type. Among girls, there were 146 of the scoliotic type and 80 of the round-shoulder and hollow-back type. Of the scoliotic type in boys, the age of greatest frequency appeared to be from twelve to fourteen, and of the girls, from ten to thirteen.

Again, grouping the cases according to the need of treatment, he found that 25 children were in great need of special treatment; 86 children could be said to be in need of special treatment; in 158, such treatment was desirable, and in 85 the treatment, although desirable, could be dispensed with without great injury to the patient. He found that although there was but little difference in the percentage of curves in girls and boys, the cases among girls were more severe than those among boys and that the muscular system, as a rule, was not as good in the former as in the latter, and for that reason it was difficult to determine precisely as to the grade of the deformity as far as the bony change was concerned.

In determining the cause of scoliosis, it was important to distinguish between the exciting causes, — as to whether this is due to what may be called the inability of the skeleton to carry its burden, — and it is important to distinguish between the static inability to withstand the weight without distorting change and the ability to carry the burden with muscular fatigue. An insufficiency of the vertebral column can either be due to a morbid condition, like rickets or a similar affection, or to too rapid growth, or can be due to the inability of the ligaments or muscles to hold the column in its proper position. Admitting the difficulty of determining this, he makes use of his own judgment in making a distinction. Taking the cases of scoliosis alone, he finds that there are 283 students out of the 1,600 ranging between fifteen and six where scoliosis existed to an extent needing consideration. The dominating scoliosis type was a primary lumbar scoliosis with more or less compensation upwards. As a rule, the scoliosis was left-sided and rarely right-sided. The connection of this scoliosis type to inequality of the legs could frequently be determined without close investigation in that the inequality of the length of the legs was so great that peculiarity in gait was noticeable. Out of 38 right-sided static scoliosis, 32 have the left leg longer than the right to an extent of ½ to 2½ cm. Of 175 left-sided static scoliosis, in 137 there was a shortening of the length of the left leg of from ½ to 2½ cm. In the other 38 cases the legs are noticed as equal. It would appear that quite a number of cases of scoliosis in schoolchildren are dependent upon an inequality of the lower extremities, and it is important to determine whether, in addition to this, there was a lack of development of one half of the body, especially on the left side. This Haglund determines by measurements in the upper portion of the body, and he finds that, of the 137 left-sided scoliotic cases, 101 had the shoulder measurement shorter on the left than on the right; of the 32 right-sided scoliotic cases with marked shortening of the right leg, 21 have a shortening of the shoulder measurement.

From this it would appear that a certain number of the habitual scoliotic cases were due to an unequal development on both sides of the trunk. Haglund uses as a means of measuring what he terms the shoulder-blade section, a line drawn from the middle line of the spinous processes to a projection on the spine of the scapula which is easily noticed on palpation and which he found to be constant.

Fully as important as the scoliotic curves are the antero-posterior or sagittal curves, which he thinks are not sufficiently investigated, for the reason that the study of the sagittal curves is an extremely difficult one, as it is not easy to establish a standard between the normal and pathological curves of this nature. There are normal, lumbar, dorsal and cervical curves, the latter being convex backwards and the other concave backwards. It is difficult to establish a normal standard of the amount of flexibility of the spine in these antero-posterior curves, as the character of motion changes in normal growth. The movement of the upper portion to a certain degree is to be regarded as compensatory. In a greater or less obliquity of the pelvis, with a corresponding degree of lumbar scoliosis, the upper curves must be influenced to a greater or less degree. The oblique position of the pelvis also would be influenced by the position of the hip, as the obliquity of the pelvis is greater if the feet are turned outward than if they are parallel.

It is important, therefore, in studying antero-posterior curves, to determine as far as possible the cause, it being established that the insufficiency of the vertebral column can be due either to affections of the bone or to special muscular weakness. The writer is inclined to regard the prevalence of the antero-posterior curves as a valuable index of the general condition of the child.

Although it is difficult in single cases to distinguish between a normal increase or diminution

of the physiological curves, it is not difficult to recognize pathological curves. These do not consist in an abnormal degree of a normal curve, but an evident alteration of the whole column and an alteration of the normal regions of the different curves and their relative motion. The transition from the physiological mobility of the different regions is such that an amount of motion can take place in the wrong portion of the spine, or the mobility can be too great or too little in relation to that seen in other portions of the spine. This is a matter which requires some experience to determine, but no more than can be obtained by any one who is accustomed to examine the spinal column in children.

Schoolchildren present three types of antero-posterior curves. In the first type, the dorsal kyphosis begins at the union of the sacrum and the lumbar vertebræ. The lumbar lordosis disappears and there remains only a slight alteration in direction, as if the whole consisted of a long curve to the upper cervical region. This curve is entirely due to muscular insufficiency and comes usually in persons of a feeble constitution, anemia or imperfect nutrition. The second type is seen especially in boys of the upper classes, where there is not infrequently a great increase of the lumbar lordosis. There may be a sharp bend; the dorsal kyphosis may be relatively small. This, however, is not always the case, as in certain instances there may be a marked dorsal curve. This is a curve which may be increased by improper gymnastic exercises. Type 3 comprises a pathological increase of the upper portion of the dorsal curve, including also a portion of the upper cervical region. This type is what is commonly called round shoulders. The kyphosis is often very rigid, and there may be a rounding from side to side. It is a very difficult form to treat and is quite injurious, as the excursion of the sternum is diminished and the respiration is interfered with. The cause of this type is not easily understood, — sitting too much with a flattened chest giving superficial respiration, adenoids, low desk and high chairs are perhaps important factors. In addition, what is called the flat back is frequently seen, that is, a back without the usual physiological curves, often with an almost straight line of the sacrum. A fifth type is round back in the upper portion of the trunk without marked kyphosis.

The writer found in examining 90 boys and 80 girls with antero-posterior curves, the largest number at the age of fifteen; that is, the largest per cent in boys at the ages of nine and thirteen, and in girls at twelve, eleven and thirteen. These were either pure antero-posterior curves or combined with scoliosis, or scoliotics in which some antero-posterior curves were noted. In more than half of the children, however, the antero-posterior curves were uncombined with scoliosis. Of these cases of a pure type, none showed an inequality of the length of the legs, nor an inequality in the shoulder measure. The first type is found more common among girls than boys, and when it occurs in boys it is more common in the younger children, but in girls more common in the older children. Type 2 is more common in boys than in girls and in boys older than nine. Type 3 is more common in girls.

The writer concludes from his investigations that the problem is not only a large one, but one which will require the combined efforts of many to solve it. He thinks that good pedagogic gymnastics every day, with out-of-door life, all under the direction of teachers of physical culture who are directly responsible for the physical condition of the children, are desirable. For treatment, it is necessary that the schoolchildren be divided into two classes: one, those which need thorough orthopedic treatment; the second, a much larger group, needs proper school hygiene. Specialists are not yet agreed as to the proper measures of special treatment. Some writers believe that corrective gymnastics alone are necessary. Some writers advocate using the Ling system of gymnastics; others, mechanical stretching appliance in preference, but Haglund considers that this question is immaterial. The kernel of the matter is that active correction should be carried out and that less stress should be laid upon passive correction; energetic treatment is a most important factor. For the ordinary group of mild cases between six and fifteen years of age he thinks no better treatment can be prescribed that the energetic Ling gymnastics. In saying this he does not mean that surgeons cannot accomplish more by more energetic measures, but that the Ling school gymnastics give sufficiently satisfactory results.

THE INFLUENCE OF RESPIRATORY FORCE ON THE FORM OF THE VERTEBRÆ.

Yansen, after a thorough study of this subject, concludes as follows: That the normal dorsal curves of the spinal column are the result largely of pull of the respiratory muscular apparatus of both sides. The spinalis dorsi muscles are essentially a muscle of inspiration, and probably also the other erector muscles of the spine, but this is less during sleep and after great fatigue or depressing influences. The forward drop of the head or a great increase of the dorsal curve diminishes the inspiratory power of these muscles. Under normal conditions the dorsal curve can serve as a measure of the strength of the back muscles, — the greater the curve, the weaker the back muscles. The inward sinking of the sternum in rachitic cases is caused by the pull of the diaphragm. An habitual scoliosis may be regarded as of respiratory origin; that is to say, if the total muscular tension of the muscular respiratory apparatus is normally balanced on both sides, the curves of the spine are normal, but if there is a difference in the two sides of this muscular pull, scoliosis results.[4]

FLAT FOOT.

It is only comparatively recently that the fact that the prevalent deformity, flat foot, is a shoe

[4] Zeitschr. für Orthop. Chir., xxv. Band.

deformity, i. e., that it is not observed in barefooted races.

Bardenheuer, after a careful investigation, confirms this view. He finds also that sandal-wearing monks, and peasants wearing loose wooden shoes, do not suffer from flat foot. Fresh recruits from the German army have a relatively high percentage of flat foot, which is reduced by the leg and foot gymnastics to which they are subjected.

His conclusions are as follows: *Valgo planus* or flat foot is an affection of great importance which interferes distinctly with the activity of the patient and indirectly and correspondingly with the general health. Flat foot is one of the most common of all surgical troubles. The cause of the trouble is the lack of correspondence between the weight of the body and the strength of the muscles. Primarily, it is due to the weakness of the muscles, and the chief cause of the muscular weakness is footwear which injures the strength of the long and short plantar muscles and of the antagonist muscles as well. The primary cause is not to be found in a change of the texture of the bones. Rickets of adolescents of the bones of the feet may, however, act as a contributory cause. The most important means of preventing flat feet is to be found in gymnastics carried out from earliest youth, especially those exercising the toe muscles, combined with instruction in normal gait; the most reliable method for the cure of flat foot is that of enforcing daily muscular exercise, thoroughly carried out. These may be sufficient to cure flat feet of a mild grade, and even in resistent flat foot an improvement in functional activity may result from gymnastics alone. Barefooted individuals do not have flat foot, as the muscles are used and thoroughly developed. Shoes should be so constructed that the activity of the plantar muscles is not interfered with. The front of the shoe should permit of proper adduction of the foot. The patient must learn to walk straight with, as far as possible, the weight falling well upon the front of the foot and especially upon the great toe, using a strong flexion of the foot and the action of supination. Persons running barefooted or wearing sandals walk with adducted feet and do not have flat feet. Hunting shoes and tramping shoes, in spite of their weight, are of aid in flat foot if they are properly constructed. The heel of the shoe should not be high and should be broad. Plates act as a means of support of the sustentaculum tali. Fixed flat foot with strong muscles and without symptoms demand no other treatment than gymnastics, but if symptoms are present, the correction of the deformity followed by gymnastic treatment is necessary. Mechanical treatment of flat foot alone never gives satisfactory results. It must always be united with gymnastic treatment, the latter constituting the most important factor of the treatment. Hallux valgus and the crowding of the three inner toes is a result of the abduction of the front of the shoe. Individuals wearing sandals habitually, i. e., monks, and peasants wearing wooden shoes, do not suffer from flat feet and have strongly developed foot muscles, especially the plantar muscles of the feet. Flat foot is not a congenital deformity, but always an acquired deformity. Flat foot in children is cured by the avoidance of shoes and barefooted locomotion. The *pes planus* of adolescence is usually developed quickly and needs the use of plates and proper functional treatment. Flat foot of adults over twenty years of age can be treated successfully among energetic people principally by gymnastic treatment, though sometimes plates are necessary.

The flat foot of adolescence, if not treated, is liable to develop the fixed contracted *pes planus*. Walking with abducted and pronated feet is especially dangerous. The so-called walking on the inner edge of the foot is quite common among persons of heavy weight [5] after forty years of age.

CONGENITAL DISLOCATION OF THE HIP.

Schanz recommends a simple method of manipulative reduction as follows: The surgeon stands on the side of the patient opposite the deformity and places one hand upon the symphysis pubis and around the affected hip. The surgeon grasping the limb at the knee, with the other hand flexes and adducts it sharply flexed. The limb is then rotated, the foot and leg being turned toward the outer side until the axis of the leg is at right angles with the longitudinal axis of the body. The head is by this maneuver brought opposite the shallowest part of the rim of the acetabulum. Under a pull with a rocking motion given to the limb, the head is rotated into the socket. Abduction is then applied, pressure being exerted on the head. In this way the contraction of the capsule is stretched.

The method is similar in theory to that recommended by Dr. Hibbs, of New York, but is simpler in not requiring the mechanism used by him.[6]

Reports of Societies.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

SPECIAL MEETING, FRIDAY, OCT. 14, 1910.

THE President, DR. GEORGE E. DE SCHWEINITZ, in the chair.

DISCUSSION ON ACUTE AND EPIDEMIC POLIOMYELITIS.

RECENT STUDIES IN THE ETIOLOGY OF ACUTE POLIOMYELITIS.

DR. PAUL A. LEWIS, of the Rockefeller Institute, read this paper by invitation.

THE LESIONS OF ACUTE POLIOMYELITIS.

DR. ALLEN J. SMITH, Philadelphia: Much of the study of this subject has been fragmentary because of the difficulty in obtaining specimens from the living child and opportunity for autopsies. The disease has been looked upon as a nervous affection, but last year the feeling of the whole profession changed and it has been ready to take up the view so well borne out by what Dr. Lewis has said, that it is a general infection with local involvements of the central nervous system, leaving behind serious alterations of the central nervous

[5] Zeitschr. für Orthop. Chir., xxvi. Band.
[6] *Ibid.*, Band xxx, 1910.

system with their sequels extending out into the muscles. More careful examinations should be made, and we need to have more data in connection with the rest of the body.

ANTERIOR POLIOMYELITIS.

Dr. Joseph S. Neff, Director Department of Public Health and Charities, Philadelphia: The results of a careful study of the reported cases of anterio-poliomyelitis in Philadelphia during the last summer demonstrate very little, with possibly two exceptions, and become of value only by adding to statistics for further deductions. The two exceptions are the parts played in the etiology by feeding, and general housing conditions. Of 99 cases in Philadelphia, 6 were breast-fed alone; 11, bottle-fed; 43, mixed-fed, and 38 partook of ordinary table-food. The disease was practically absent in the wards of the city with the highest congestion of population, and the only location showing apparent grouping of cases has the lowest ratio (excepting suburban wards) of population per acre. The study tends to show that general sanitation, crowding and housing conditions do not play a part, at least in Philadelphia, in the etiology of the disease. From observation of all the cases reported it is evident that poliomyelitis is very mildly contagious and much less so than other so-called children's diseases.

Especial attention is called to the fact that the week ending July 23 and the week ending Aug. 6, in which the greatest number of cases occurred, followed the hottest weeks of the summer. The main point to be taken into consideration by health officials, until more definite knowledge of the cause and spread of the disease is obtained, is the means of prevention. Their duty is to prevent the spread of disease, but at the same time the welfare and comfort of the community must be considered. The questions involved are as to isolation, quarantine, exclusion from school of other children in the family, placarding, etc. Up to the present time, and in view of the approaching cold weather, the health authorities of Philadelphia have done nothing further than to order isolation of the patient and the disinfection of all discharges. My own thought is to await developments next spring. Should we have isolated cases only, no further action will be needed. Should the disease become epidemic, my present thought is to compel isolation of the patient, exclude from school other children in the family for a period slightly beyond the period of incubation of the disease, and give written instructions as to the disinfection of all discharges, but I do not believe it will be necessary to placard the house. There seem to be as many secondary cases where isolation has been maintained as where it was not attempted.

SPECIAL FEATURES IN THE SYMPTOMATOLOGY AND TREATMENT OF ACUTE POLIOMYELITIS, WITH SOME DISCUSSION OF ITS PROBABLE PATHOGENESIS, BASED CHIEFLY UPON STUDIES MADE DURING THE RECENT EPIDEMIC.

Dr. Charles K. Mills: In my opinion the probable cause of acute poliomyelitis is some form of protozoon, which is perhaps carried by an insect to be found in the neighborhood of the prevailing epidemic. In the fulminant cases meningitis is commonly present and may be severe; in other cases it is transient, and often absent. In several cases which have come under my observation death has occurred with evidences of involvement of the bulb. Paralysis involving one or two of the ocular muscles has been present in some instances. In one case a moderate degree of facial paralysis was the only residual palsy. A second recrudescence of the acute symptoms was seen in several cases. My investigations show the period of incubation to be usually from one to two weeks. Prognosis as to residual paralysis in the cases I have seen has been relatively bad. In treatment I would advise the use of urotropine in the acute stage; febrifuges, fluid extract of ergot, the large Bier's cups, calomel with salines and rest when possible on the side or in the prone position. Massage or electricity should not be used for several weeks after onset, and such treatment should be conservative in character. As a rule operative procedure should not be carried out for several months. Occasionally some kind of support to prevent possible deformity is advisable.

Dr. B. Franklin Royer, Harrisburg: The studies made by the Department of Health lead to the suggestion that the disease is a systemic one, showing only occasionally paralysis as a symptom. Some of the cases show fever and go no further. From the standpoint of some observers deaths attributed to bronchopneumonia in which the fever has been high were in reality due to poliomyelitis.

Dr. F. X. Dercum: Holt and others have come to the conclusion that the contagion is spread by human carriers not in themselves infected. The mucous membranes and the digestive tract should receive special attention, and certainly the close contact of children who are ill should be avoided.

Dr. J. P. Crozer Griffith: Danger comes from the abortive cases because of the inability to recognize them. Therefore, some test by which these cases can be determined should be devised.

Dr. Hobart A. Hare: I believe that if the physician will simply attend to the ordinary hygienic measures the recoveries will be far greater in number than with the active medication of the patient. After the sharpness of the attack, attention may be paid to strengthening the partially destroyed cells.

Dr. John K. Mitchell: I believe that damage is done by too early and too severe treatment. Physicians should not yield to demands of parents that something be done, but should insist that six weeks or two months be allowed before special measures are used. He should particularly avoid the ordinary mistake of allowing the child to sit up too soon. I have seen lateral curvature the result of this mistake. Electricity should not be used under six or eight weeks, and there should not be discouragement from getting no result in the early treatment. The only satisfactory rule about the use of electricity is that the current that will produce the result is the one we want to use.

Dr. John B. Roberts: I understand that this disease is believed to be transmitted usually by infection through the nasal and faucial mucous membranes. If this theory is correct, is it not a physiological error to encourage or adopt the prevalent practice of total extirpation of the faucial and pharyngeal tonsils in children in whom there is inflammation and hypertrophy of these organs? The glossal, faucial and pharyngeal tonsils are adenoid structures apparently placed as sieves or guardians of the alimentary and respiratory tracts to arrest the entrance of micro-organisms into the general circulation. The occurrence of poliomyelitis more frequently in children of the well-to-do than in those in the lower walks of life may perhaps be due to the fact that such well-born children are now-a-days deprived by operation of these organs more commonly than the children of the poor.

Dr. William G. Spiller: I have seen one case in which lumbar puncture with the removal of an ounce and a half of fluid relieved the intense pain and the difficult breathing.

Dr. Henry W. Cattell: That which is done abroad to a very large extent is the application of a plaster of

Paris cast to maintain a proper position of the child in bed.

DR. ALFRED GORDON: The manner of transmission of the disease and the resistance of the virus to cold are important factors in prophylaxis.

DR. DAVID REISMAN: One cannot escape the view that infantile paralysis is one of the transmissible diseases. Even though the contagion may be slight, in view of the terrible nature of the disease, all possible precautions against its transmission should be taken. It has also occurred to me that some of the cases of polio-encephalitis occurring sporadically in children and in adults may have the same etiology as anterior poliomyelitis. A short time ago I saw with Dr. Hand a man, also seen by Dr. Mills and Dr. Spiller, who seemed to be suffering from an hyperacute attack of polio-encephalitis, the first symptom having been facial paralysis. I have also in mind another case of polio-encephalitis, that of a little boy of eight, who after a desperate illness made an almost complete recovery. Nothing remained except diplopia, due to a weakness of the external rectus. It may be, from an epidemiological standpoint, very important to trace the relation of these cases to epidemic anterior poliomyelitis.

Book Reviews.

A Plea for the Home Treatment and Prevention of Scarlet Fever. By ROBERT MILNE, M.D., Ch.M., Medical Officer of Dr. Barnardo's Hospitals and Homes for thirty years, etc. Pp. 80. New York: William Wood & Co. 1910.

This little book is a presentation of Dr. Milne's claim that, if patients with scarlet fever are annointed with eucalyptus oil and have their tonsils swabbed with one to ten carbolic oil, isolation is unnecessary. This is either a wonderful discovery or an error in observation!

Gynecological Diagnosis. By WALTER L. BURRAGE, M.D. Pp. xvi, 656; 207 illustrations. New York: D. Appleton & Co. 1910.

In this volume of over six hundred pages Dr. Burrage has produced what seems to your reviewer a model for works of its kind. As the title implies, the writer has chosen to confine himself strictly to diagnosis, — there is not a word as to treatment from cover to cover, — and the field has been covered with a thoroughness and the writer's views expressed with a clean-cut terseness that make the book very pleasant reading. It is probable that it was designed primarily for the student, but we feel sure that it will appeal quite as strongly to men who have been in practice for years.

The first ten chapters are devoted to methods of examination and, as might have been expected from a man with Dr. Burrage's keen insight into the meaning of symptoms, there are two extremely readable chapters upon the interpretation of the clinical history and the significance of the chief symptoms of pelvic disease, — the latter a godsend to the perplexed physician, — and throughout the book stress is constantly laid upon the meaning of symptoms. The chapters upon the physical examination and the armamentarium are eminently practical and contain many hints as to special technic suggested by the writer's experience. We note rather with surprise that the author does not approve of the routine use of rubber gloves for examination, being ourselves accustomed to think that they do not interfere with the tactile sense to any appreciable degree and that their use is an added safeguard both to patient and physician.

The rest of the book is devoted to special diagnosis, and very wisely, we think, the writer has devoted considerable space to certain matters that are generally more or less slighted in gynecological works, such as diseases of the rectum and of the breast, — the latter surveyed of necessity in rather a cursory manner, — an excellent chapter upon the diagnosis of the gynecological affections of infancy and childhood, and another, equally good, upon the menopause and old age, containing a suggestive résumé of the physical conditions present in 115 cases at the menopause occurring in his own practice. Dr. Burrage emphasizes strongly the vital importance of the prompt investigation of all symptoms occurring at this period of a woman's life, instead of following the all too common and dangerous practice of ascribing almost everything to the "change of life."

Considering the chapters on special diagnosis somewhat in detail, we note that the author has throughout avoided burdening the book with overmuch pathology, although at the beginning of each chapter we have the essentials of the pathology of the subject under consideration and a résumé of the latest views about it. We were also struck with the graphic account given of various types of gynecological disease, e. g., that of pelvic inflammation. A thoughtful chapter upon the causes of prolapse will well repay reading, as will also that upon ovarian tumors. We note that the author follows the excellent Pfannenstiel classification of these tumors. The chapter upon diseases of the vulva contains much that is generally to be found only in special works. The chapter upon the diagnosis of pregnancy is exceptionally good and strictly up to date, as, for instance, in the reference to the work of Underhill and Rand upon the changes in the urine in the pernicious vomiting of pregnancy. The great interest that Dr. Burrage takes in the diseases of the bladder and ureters is shown by the two very satisfactory chapters upon those subjects. Here, as elsewhere, we are struck by the constant warning of what not to do. We recognize with sorrow that the sins of the would-be gynecologist are quite as frequently those of commission as of omission.

As a whole, the book is an excellent piece of bookmaking. An alphabetical index of illustrations is valuable, as is also the system of having each chapter headed by a résumé of its contents with page references. While not padded with unnecessary illustrations, the book contains quite sufficient, including many excellent original ones by Miss Spaulding and Miss Heustis.

We feel that this book is a distinct addition to our working library and hope that its well-merited success will spur the writer on to prepare a companion volume upon gynecological treatment.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, NOVEMBER 24, 1910

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter payable to

W. M. LEONARD,

THE ABOLITION OF PUBLIC ABOMINATIONS.

In an editorial in the issue of the Journal for Oct. 13 on "Some Public Abominations," we referred to the common roller-towel as one "whose abolition should go hand in hand with that of the public drinking cup." Interesting confirmation of this statement is found in a recent bulletin of the New York State Health Department at Albany, N. Y., which says: "The public drinking cup must be branded as a public nuisance and must give way under the weight of public opinion enforcing the conclusions of the sanitarian; and with the common drinking cup ought to go the common towel, which at times may prove even more dangerous than the common cup." It is evident that the gospel of public hygiene is making converts. Anent the abolition of public cups in Massachusetts, it is also interesting to note a recent letter to the daily press from a correspondent who suggests that the continued use of common communion cups in churches is a violation of the new ordinance and pertinently queries whether "the church that persists in the use of the single cup in the communion service" does not "deprive many thinking people of the very help and comfort offered them." At the time when the bill for the abolition of common drinking cups was pending before the state legislature, we published in the issue of the Journal for March 31, 1910, under the heading of "Religious Opposition to a Hygienic Measure," a note calling attention to this very matter of the communion cup as furnishing to certain people a ground of objection to the proposed law. That law has now gone into effect, and it should seeem that, with all due respect to tradition and sentiment, its provisions might properly be enforced in the church as well as in the market place.

In other matters as well as in that of drinking-cups there seems to have been recently in Boston a local recrudescence of interest in certain public abominations. One of the irritating and dangerous abominations, associated with the dryness of our climate, is that of the dust which, in the absence of rain and the presence of wind, fills our city streets with choking and irrespirable particles, and our respiratory tracts with foreign bodies and assorted bacteria. Dust is one of the most potent agents in the dissemination of pulmonary disease and of chronic nasopharyngeal disturbances predisposing thereto. Neither street-watering nor oiling avails to check it more than temporarily. Now it is reported that the superintendent of streets in Boston is about to try for this purpose a new chemical preparation, presumably calcium chloride, which by its deliquescence keeps the streets moist by drawing water from the atmosphere. Such a preparation has been tried in several large American cities with considerable success. At any rate, the abolition of public dust would be a worthy hygienic achievement.

Finally, we have had in Boston during the past week a renewed crusade for enforcement of the statute against promiscuous public expectoration, — a "spit war," as it has been euphemistically designated by the yellow press. A general order was issued by the police commissioner directing more rigorous enforcement of the law, with the result that a number of arrests were made and a number of offenders fined $2 each. Various humorous incidents occurred during this campaign. One offender, who was fined only $1, remarked that it was cheaper to spit in his quarter of the city than elsewhere. Another, an Italian, on being searched after his arrest for spitting, was found to be carrying a loaded revolver; he was fined $2 for expectoration and $25 for carrying a concealed weapon. It might prove a valuable augmentation to the public treasury to arrest and search all citizens periodically. Most exquisitely subtle and ironical of all was the suggestion that women, children and the poor and ignorant be not arrested for spitting, but only well-dressed gentlemen. *Noblesse oblige encore.* After all, the anti-spitting crusade, though as yet of too short duration to produce notable change in public manners, has been interesting and profitable, and, if it turns out to be more than a transient burst of enthusiasm, may prove a genuine step towards the abolition of one more public abomination.

ONE ASPECT OF VENEREAL PROPHYLAXIS.

SOME of the phases of venereal prophylaxis touch unexpected places in the social fabric. One is the question of the division of responsibility between the individual who has contracted venereal disease and society which has permitted his infection. It happens that in the navy this is far from being an academic question, because the very practical matter of determining whether a man with venereal disease shall be considered to have received his infection "in line of duty" or otherwise comes frequently before medical officers, and their decision is of much importance both to the individual and to the service. It is the practice to consider venereal disease as contracted "in line of duty" only in those cases, which are by no means uncommon in the navy, in which infection has been innocently acquired. Perhaps this is the only just way, and yet the fact is being recognized more and more clearly that there is a certain responsibility, if not actual liability, which rests with the naval service for the enlisted man who becomes infected with venereal disease while serving his country afloat.

In an exceedingly interesting article in the *United States Naval Medical Bulletin*, Passed Assistant Surgeon Heber Butts discusses the justice of regarding general paresis as a disease which may be contracted in "line of duty." Since 1899 twenty-seven cases of general paresis have been admitted to the Government Hospital for the Insane from the active lists of the Navy and the Marine Corps. Seventeen of these cases were given "line of duty" in the reports of medical boards of survey. But practically all cases of general paresis give a positive Wassermann reaction, and Dr. Butts says that it seems fair now to conclude that cases of general paresis should be given "line of duty" only if positive evidence is furnished that syphilis was innocently acquired. If the mode of infection is to remain the test in cases of syphilis which do not result in general paresis, it seems only fair to apply it when that disease occurs.

At first thought it seems absurd to hold that the government is responsible at all for the enlisted men of the navy who contract venereal disease, and yet Dr. Butts shows that it is by no means easy to say just where the responsibility of the individual ends and the responsibility of the service to the man commences. He takes, as an instance, a farmer boy who enlists at some inland recruiting station as a coal-passer. "The navy takes him out of an environment in which, it may be assumed, prostitutes are few or unknown, and there is comparatively small danger of his becoming infected with syphilis. Sooner or later in the course of his service he is taken to an environment, — perhaps to the Orient, — to the fabled land 'east of Suez,' where he is told 'there ain't no Ten Commandments,' where syphilis is rife, where prostitutes are many, and where the restraining influences of father, mother, sister and sweetheart are removed. He frequently finds time passing slowly; clean places of amusement are few or absent; he feels an impulse while in Rome to 'do as the Romans do,' and the army of prostitutes which frequently follows a fleet like birds of prey exerts an influence amid conditions which in his home community did not exist. The responsibility for the acquisition of syphilis, general paresis or tabes by that young man may not be entirely his own. The naval service should share in it, I am convinced, though not to the degree of giving him 'line of duty' and a pension. That responsibility, too, on the part of the naval service increases according to the degree to which it is possibly able to protect its personnel from syphilitic and parasyphilitic diseases and fails to do so. The greater the opportunity to protect, the greater the responsibility."

One cannot help applying this to conditions in civil life. The young farmer whom Dr. Butts takes for his example might have gone to a distant city to make his way instead of enlisting in the navy. He would have lost the protecting influence of his mother, his sisters or his sweetheart in nearly the same degree, and temptation might come to him there in nearly as attractive guise and nearly as insistently as in the navy. Of course if he yielded and became infected with syphilis, a very large share of the responsibility would rest with him, but only the most superficial reasoning could convince one that some share would not rest also with the community which either neglected its "social problem" altogether or else turned it over to corrupt authorities to solve in the manner which would yield the largest return of financial gain or political profit.

In the navy the responsibility is recognized, and there is a growing tendency to meet it by providing proper recreation for the enlisted personnel and by an energetic and very successful effort to limit infection by applying prophylactic treatment to those who have been exposed. It is a question whether in civil life we have recognized our responsibility so clearly or considered very seriously the adoption of measures to prevent infection. Probably it is too radical to sug-

gest that dispensaries should be established in certain parts of the city where young men who have been exposed might secure preventive treatment at any hour of the day or night by methods which have proved so useful in the navy, but, if we admit that the community has even a small part of the responsibility which is so freely recognized in the naval service, it is difficult to find the most logical reasons why no such efforts should be made.

ADMINISTRATION OF THE ROCKEFELLER FOUNDATION.

In the issue of the JOURNAL for March 10, 1910, we commented editorially on the establishment by Mr. Rockefeller of the Rockefeller Foundation. Plans for the incorporation of this foundation are still in progress. In an address last week before a session of the National Association of State Universities at Washington, D. C., President Schurman, of Cornell University, criticised the terms of the charter as proposed in the bill now before the national legislature whereby the administration of the fund is placed in the hands of a self-perpetuating board of trustees. Instead, he suggests a governing board similar to that of the Smithsonian Institution, which has a board of regents composed of the Vice-President and the Chief Justice of the United States, three members each of the Senate and of the House of Representatives, "together with six other persons, other than members of Congress, two of whom shall be resident in Washington and the other four inhabitants of some state, but no two of the same state."

The disadvantages and possible dangers of either method of administration are obvious. Whichever be selected, it is important that the control of so vast a fund, with such enormous possibilities for public good or evil, be determined only after mature deliberation and sagacious counsel.

SPREAD OF ANTITYPHOID INOCULATION.

THE experience of the Massachusetts General Hospital in the control of typhoid infection among its nurses and ward-tenders by means of antityphoid inoculation has already led to the adoption of voluntary inoculation among nurses and internes of several other hospitals in Boston. As we have several times pointed out in the columns of the JOURNAL, the procedure is simple, free from danger, produces little or no inconvenience and apparently affords a high degree of immunity against the disease. Not to take advantage of such a valuable discovery in preventive medicine is indicative of either inertia, prejudice or unreasonable fear. It is probably too much to hope as yet for the establishment of compulsory general antityphoid inoculation, but the spread of voluntary inoculation is gratifying and should be continuous. Physicians and nurses should be the first to set in their own persons, and in those of their families, an example of intelligence and progressiveness; and physicians particularly should explain to their patients the nature of the inoculation, and should urge upon them the adoption of this wise and beneficent measure of self-protection. Those who know best the dangers of typhoid should lead in the attempt at its extermination by prevention.

DECLINE OF NATURAL INCREASE OF POPULATION IN THE UNITED STATES.

THE latest bulletin of the United States Census Bureau presents the data of population in the states of Rhode Island, Michigan, Missouri, New Mexico, Delaware, Vermont and Massachusetts. During the decade from 1890 to 1900 these states showed an aggregate increase in population of 18.4%; from 1900 to 1910 their increase has been only 14.9%. Assuming that they are fairly representative of the entire Union in quality and distribution of population, and that the total rate of increase throughout the United States in the past decade has been approximately 15%, — though such assumptions are justifiable only for purposes of speculation, — the total population of this country in 1910 may be expected to be about eighty millions, an increase of fourteen millions since 1900. But of this increase about one half has been due to immigration, so that the actual natural increase in population would be only seven millions, or about 10%. This is about the same rate as that of England, and considerably lower than that of Germany. In the United States the excess of births over deaths has steadily declined since 1850, and at its present rate of decrease our population, without immigration, would become stationary by 1950. Until the completion of the data of this census, such comparisons are purely hypothetical, but it seems probable that the decline of natural fecundity is as well marked in our country as among other English-speaking peoples, though not yet so far advanced as in France. What this probability

may portend in ultimate racial development, no human judgment can forecast. From the analogy of other national histories, however, it should seem to indicate the inevitable future supplanting of our race by aliens as inheritors of our language, institutions and ideals.

PROPORTION OF PHYSICIANS TO POPULATION IN GERMANY.

Overcrowding of the medical profession seems not to be confined to large eastern American cities, or even to the United States. A recent report by the United States Consul-General at Dresden indicates that in many parts of Germany the number of physicians has shown a much greater proportionate increase than the total population. During the twenty years from 1883 to 1903 the population of the Province of Brandenburg increased 55%, and the number of doctors increased 302%. In Posen the increase during the same period was 17% and 106% respectively, and in Berlin 69% and 155%. In Saxony from 1883 to 1906 the population increased about 48% and the physicians nearly 126%. Even so, however, the ratio of physicians to population is not as high in Germany as in many American cities. In Berlin at present there is one doctor of medicine to 776 inhabitants; in Saxony, one to 2,016; in West Prussia, one to 3,102; in Posen, one to 3,246; in Reuss, one to 3,723. After all, overcrowding is only a relative term, and keenness of competition, or rather emulation, should result in the medical profession, as elsewhere, in the evolution of higher types of efficiency through the process of selection.

THE CARNEY HOSPITAL AND THE RETIREMENT OF SISTER GONZAGA.

It is announced that Sister Gonzaga, for thirty years associated with the Carney Hospital in Boston, and sister superior since 1889, has been transferred by the head of her order to Baltimore. During her incumbency as sister superior she has been virtually the head of the hospital, combining, in a way, the duties both of superintendent and trustees. It is largely due to her progressive spirit that the Carney Hospital has shown the remarkable development of the past few years.

On April 1, 1891, an addition to the hospital was opened at a cost of $148,082.75, and in 1901, a new out-patient department building at a cost of $91,000. A little later a new lighting and heating plant, a laundry, mortuary and stable were added to the hospital equipment. Boilers, dynamos for power and light and a new elevator have been installed this year. These additions to the hospital have demanded the raising of a considerable sum of money, in which Sister Gonzaga has taken an active part. Even more important than these material additions to the hospital plant was the creation, eight years ago, of a continuous single headed surgical service, to which Dr. John C. Munro was appointed and which he still holds. At about the same time a similar service was established for the orthopedic department under Dr. J. E. Goldthwait and later under Dr. C. F. Painter. Three years ago a continuous medical service was instituted under the charge of Dr. Henry A. Christian, and two years ago a similar gynecological service under Dr. F. W. Johnson. The establishment of these various services was very largely due to the influence of Sister Gonzaga, who saw in this method of hospital organization an opportunity for increased efficiency. These continuous services were the first to be established in this community, although other hospitals are by degrees adopting a similar plan. It should be borne in mind that this policy at the Carney Hospital was instituted with no idea of increased efficiency for medical instruction, since at that time the hospital had no medical school associations.

During her long period of service as the head of the hospital Sister Gonzaga selected the staff without reference to religious belief, and thereby made it one of the most progressive in the community. She leaves with every regret on the part of the staff. It is to be hoped that her successor will continue her policies, particularly in selecting the best available men for staff positions in a non-sectarian spirit.

MEDICAL NOTES.

Award of Nobel Prize for Chemistry. — Report from Stockholm states that the Nobel prize for chemistry has recently been awarded to Prof. Otto Wallach, of the University of Göttingen.

Alleged Fever Temperature of 116°. — From Maysville, Ga., comes an entirely unauthenticated press report of a patient in that city who had a temperature of 116° F. Such mythical statements may well be taken with the same incredulity accorded to accounts of babies weighing over fourteen pounds at birth.

A Suspected Case of Leprosy in a Laundryman. — Report from Passaic, N. J., states that on Nov. 16, Mark Lee, a Chinese laundryman of that city, was taken to the isolation hospital as a leprosy suspect. His laundry has been fumigated, all the clothing therein sterilized and the carriage in which he was driven to the hospital has been burned.

A Tuberculosis Hospital for New Brunswick. — Mrs. James C. Jordan is reported to have presented the New Brunswick government with an estate at River Glade, valued at $30,000, to be used as a tuberculosis hospital.

A Living Centenarian. — Mrs. Thomas Chase, of Everett, Mass., is said to have been born on Nov. 17, 1810, in Warner, N. H. She was married in 1829 and has had six children. Her health is at present excellent, and her interest in current events unabated, though she is reported not to care for "modern amusements."

The Typhoid Epidemic at Annapolis. — The epidemic of typhoid fever among naval cadets at Annapolis, Md., which we noted in the latest issue of the Journal, has extended. During the past week, seven new cases which developed at the academy were sent to the naval hospital, and four other cadets are under quarantine suspected of having the disease. The source of the infection has still not been determined, and its origin seems the more unaccountable since there is not at present a single case of typhoid in the city of Annapolis.

Two Centenarians. — Peter Borry, who died last week at Reading, Pa., was locally reputed to have been born in 1808. He spent his entire life on a farm and is said to have attributed his longevity to moderation in the use of alcohol and tobacco. Many equally temperate men, however, have failed to live as long.

Mrs. Lucinda Adams, who died last week in Johnstown, N. Y., is said to have been born on Nov. 24, 1808. Her general health, vision and memory are reported to have been unimpaired until a fortnight before her death. In her later years she became particularly fond of motoring, and was much interested in aviation. She is survived by six children, sixteen grandchildren and twenty-two great-grandchildren.

"Osler in Chinese." — It is stated on the authority of the *London and China Telegraph* that Osler's "Principles and Practice of Medicine" has been translated into Chinese by the president of the China Medical Missionary Association at Shanghai. It is said that this is the only authoritative work on the practice of medicine as yet available for the Chinese in their own language. Translations of various other medical works are also in progress, among them an Atlas of Anatomy, which, presumably, will be of special value since dissections of the human body are not yet permitted in China.

Appeal for Red Cross Endowment Fund. — The Red Cross Society of America has made an appeal to the public for contributions in small amounts towards the sum of $2,000,000 which it is desired to establish as a permanent fund for the endowment of the society. A general committee has been appointed in charge of the subscriptions, with a sub-committee in each of the principal cities of the Union. The value of the work done by the Red Cross in times of peace as well as of war is unquestioned, and the nobility and integrity of its purposes unassailable.

Dr. Grenfell in Boston. Work of Miss Holman. — In the issue of the Journal for Nov. 3, we commented editorially on Dr. Grenfell's romantic and beneficent work among the natives of Labrador and the north. Dr. Grenfell arrived in Boston on Nov. 20, and will remain for a short time in this vicinity, making several public addresses relative to his work and the increasing possibilities of its service. In December, he will sail for England and will return thence in May to Labrador.

A work similar in kind to Dr. Grenfell's, though very different in environment, is that which for the past eight years has been done by Miss Lydia Holman, a nurse among the mountaineers of North Carolina. At a meeting of the Twentieth Century Club in Boston last week this heroic woman told the story of her hardships, efforts, successes and failures. During this time she has covered day and night in all sorts of weather, alone and often on horseback, a territory of sixty square miles, ministering to and relieving and endeavoring to teach an ignorant and superstitious peasantry. Her present project is the establishment of an infirmary and social settlement for the aid and extension of her work, an undertaking in which she should have the warmest support and encouragement.

Vaccination Laws in Germany. — The present vaccination laws of Germany, enacted in 1884, make it compulsory for every person in the empire to be vaccinated not only in infancy, but again at

the age of eight and again at eighteen. Since this regulation has been in force, there has not been a single death from smallpox in the German army. This fact, which is eloquent testimony to the efficacy of protective inoculation, may well make the medical profession in America envious of the laudable stringency of German law. The paternalism of Teutonic government makes it an effective machine in medical prophylaxis.

Smallpox among the Arapahoes. — In a recent issue of the Journal we commented on the well-known peculiarly malignant virulence assumed by certain infections among aboriginal peoples. During the four days from Nov. 14 to 18, ninety-three Indians are reported to have died from a sudden epidemic of smallpox on the Arapahoe Reservation near Cheyenne, Wyo. Doubtless the rapid fatality of this always dangerous disease is favored by the ignorance and prejudice of the Indians, but it seems at least in part an evidence of the high susceptibility to pestilential infections of our native tribes.

Problems of the Opium Traffic. — At the annual session of the National Association of Wholesale Druggists, held last week at Dallas, Tex., Charles A. West, of Boston, chairman of the committee on legislation, recommended "an international tax on opium manufactured for smoking purposes." It is to be presumed that this suggested law is intended to be prohibitive in its action. The Association voted to hold its next meeting in October, 1911, in New York City.

In this connection it is interesting to learn of the alleged preparation by the Chinese of an appeal to Great Britain to abrogate the two treaties which give private British interests the right to engage in the opium trade. Ostensibly this request is for the purpose of diminishing the amount of illicit traffic in the drug. Actually one cannot help suspecting the motives of a people to whom complete control of the opium market would be a source of considerable wealth.

Name of Parent Substances of Derivative Not Required on Label. — Druggists and manufacturers under the pure food law are not required to name the parent substances of a derivative when they state on the label the name and quantity of the derivative, according to the decision of Chief Justice Clabaugh in the Supreme Court of the District of Columbia. The Court held that the secretaries of Agriculture, Treasury and Commerce and Labor, upon whom the law imposed the duty of making regulations to carry out the act, exceeded their authority when they attempted to require the manufacturing druggists to add to the name of the derivative the fact that it is derived from a parent drug, such as alcohol, cocaine, acetanilid, etc. Such action the court determined to be legislation and not regulation.

Two Neoplastic Lovers. — The following item, sent us by a correspondent, revives memories of an ancient medical witticism, whose unfamiliarity to a modern generation of young physicians may perhaps justify its repetition:

"James Payn, the novelist, was editor of the *Cornhill Magazine*, London. Next door to his office a medical journal had its sanctum. One day Mr. Payn's door was cautiously opened. 'I have brought a little thing about sarcoma and carcinoma,' said the visitor. 'Very sorry, sir,' said Payn, politely, 'but we have all the poetry we want.' 'This isn't poetry!' exclaimed the visitor. 'It is an essay on two varieties of tumor.' 'Oh, I beg your pardon,' said Payn. 'I thought they were a pair of Italian lovers.' The visitor was a well-known medical professor who had entered the wrong office."

Probably the stories of Paul and Virginia, or Gracieuse and Percinet, were too fresh in the editor's recollection to make him desire more of the same.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston.— For the week ending at noon, Nov. 16, 1910, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 41, scarlatina 28, typhoid fever 9, measles 20, smallpox 0, tuberculosis 67.

The death-rate of the reported deaths for the week ending Nov. 16, 1910, was 16.56.

Boston Mortality Statistics.—The total number of deaths reported to the Board of Health for the week ending Saturday, noon, Nov. 12, 1910, was 181, against 173 the corresponding week of last year, showing an increase of 8 deaths, and making the death-rate for the week, 14.01. Of this number 97 were males and 84 were females; 177 were white and 4 colored; 114 were born in the United States, 65 in foreign countries and 2 unknown; 44 were of American parentage, 115 of foreign parentage and 22 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 51 cases and 2 deaths; scarlatina, 39 cases and 1 death; typhoid fever, 19 cases and 3 deaths; measles, 16 cases and 0 deaths; tuberculosis, 51

cases and 20 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 30, whooping cough 1, heart disease 28, bronchitis 5. There were 10 deaths from violent causes. The number of children who died under one year was 24; the number under five years, 38. The number of persons who died over sixty years of age was 64. The deaths in public institutions were 56. Cerebrospinal meningitis, 1 case. Anterior poliomyelitis, 1 case.

Of the above infectious diseases the following were non-residents: Consumption, 2 cases and 1 death. Typhoid fever, 1 case and 1 death. Scarlet fever, 6 cases. Diphtheria, 4 cases and 1 death.

Deducting deaths of non-residents, the total is 172 and the death-rate is then 13.31.

Reappointed Medical Examiner. — Orland J. Brown, M.D., of North Adams, Mass., has just been reappointed by Governor Draper, Medical Examiner for Berkshire County. The appointment is for a period of seven years, and this is Dr. Brown's fifth consecutive term of service.

An American Elected to Berlin Academy of Science. — Report from Germany announces that William Morris Davis, professor of geology in Harvard College, has recently been elected a member of the Berlin Academy of Science.

Penalty for Practising without Registration. — In the municipal court last week Jeremiah Scopa, of East Boston, was fined $100 for practising medicine without being registered under the laws of the Commonwealth of Massachusetts. He was subsequently held in $1,000 bail for the grand jury on a charge of perjury.

Successful Candidates for Registration in Dentistry. — Of 81 candidates who took the examinations in October last before the Massachusetts State Board of Registration in Dentistry, 25 passed and are now entitled to practise their profession in this Commonwealth.

Hospital Concerts for December. — It is announced that during the month of December the concerts of the Hospital Music Fund will be given as follows: On Dec. 4, at the Channing Home, Brookline; on Dec. 11, at the New England Hospital for Women and Children, Roxbury; on Dec. 18, at the Cambridge Hospital; and on Dec. 25, at the Massachusetts Homœopathic Hospital, Boston.

Proceeds of Several Fairs. — At the fair held in Boston last week by the Board of Directors of the Blind Babies' Aid Society, several thousand dollars were realized for the benefit of the Boston Nursery for Blind Babies. At a fair held three weeks ago in Boston, the sum of $1,100 was raised for the Woman's Charity Club Hospital. The Nurses' Club of Boston had a sale last week, the proceeds of which are to be devoted to furnishing the rooms of the club.

Some Recent Bequests to Hospitals. — Among numerous bequests to public charitable institutions, in the will of the late Anna Healy, filed for probate in Boston last week, were legacies of $5,000 to the Carney Hospital and $2,000 to the Free Home for Consumptives.

The will of the late Mrs. Daniel Dempsey, of Woonsocket, R. I., filed for probate in that city on Nov. 14, makes a bequest of $5,000 for the maintenance of a free bed in St. Joseph's Hospital at Providence, R. I.

Meeting of the Milk and Baby Hygiene Association. — At the annual meeting of the Milk and Baby Hygiene Association of Boston, held last week, Dr. Arthur A. Howard was elected medical director for the ensuing year. The report of the director, Mr. Kruesi, emphasized the part taken by the Association in procuring the prohibition of the sale of "loose milk" in Boston, and in securing the establishment of scientific research into some of the problems of the milk feeding of infants. This report further recommended the presentation, advocacy and support by the Association of a bill before the Massachusetts State Legislature forbidding "the employment of women in industry for two weeks before and six weeks after childbirth." A similar measure has been operative in Switzerland since 1877.

Protest against Condemnation of Bob-Veal. — In the issue of the Journal for Nov. 3 we noted the recent condemnation by the Boston Board of Health of a shipment of bob-veal as unfit for food. At a meeting last week of the New England Live Stock Dealers' Association, the president was authorized to appoint a committee of five to confer with the Massachusetts State Board of Health, with the United States inspectors and with the cattle commissioner in regard to a repeal of the present law governing the sale of veal in this state.

Reunion of Jefferson Medical College Graduates. — At a reunion of New England graduates of the Jefferson Medical College, held in Boston last week, addresses were made by

Walter A. Ballantyne on "Sanitary Problems of To-Day," and by Dr. Alfred Worcester, of Waltham, Mass., on the invaluable service done by nurses in the campaign against tuberculosis. Among the other speakers were Dr. John C. Berry, of Worcester, Mass., and Dr. John E. Donley, of Providence, R. I.

A REMINISCENCE OF DR. LANGE'S VISIT. — In an address before the annual meeting of the Board of Directors of the New England Peabody Home for Crippled Children, held in Boston last week, Dr. Robert W. Lovett spoke of the praise accorded to the work of this institution by Dr. Fritz Lange, of Münich, at the time of the latter's visit to this country last spring. In the issue of the JOURNAL for April 7, 1910, we commented editorially on Dr. Lange's distinguished position as "one of the leading authorities in Germany on orthopedics." His commendation is gratifying and complimentary not only to the institution in question, but to American orthopedic surgery.

PROPOSED COMMISSION ON PUBLIC HEALTH. — There has recently been filed with the clerk of the Massachusetts House of Representatives, for introduction at the next session of the State Legislature, a bill providing for the abolition of the present State Board of Health and the establishment in its stead of a salaried Commission on Public Health, to be composed of three persons appointed by the governor, who would devote their entire time to the work, and who, in addition to other duties, would be given "supervision of the inland waters and water-supply of the Commonwealth."

This proposed measure seems to represent the local resentment of a certain municipality (Lynn) against the present State Board of Health over the installation of a plant for the purification of water. As the legislator who proposes it has just failed of re-election by his constituency, the bill probably hardly needs serious consideration.

NEW YORK.

HOME FOR NURSES, JEWISH HOSPITAL. — The new home for nurses of the Jewish Hospital, at Classon Avenue and Prospect Place, Brooklyn, was dedicated on Nov. 6 with appropriate ceremonies. The building cost $100,000, and is very thoroughly equipped.

ARRESTS FOR MOTOR CAR SMOKE. — Health Commissioner Lederle announces that since Sept. 29, when the active enforcement of the ordinance was first put into effect, 365 arrests have been made for violations of the Sanitary Code forbidding the escape of dense volumes of smoke from the exhaust pipes of motor cars; that 286 of the offenders have been fined; that 47 are under suspended sentences, and that but 32 have been discharged.

NEW YORK MILK COMMITTEE. — The New York Milk Committee will hold a conference for the purpose of discussing the most efficient ways of controlling the municipal milk supply in New York City, Dec. 2 and 3. There will be four sections: Milk Economics, Milk Supply and the Public Health, Milk Standards, and Milk Commissions. Physicians, sanitarians, research workers and representatives of the municipal, state and national health and agricultural departments will be present. The meetings will be thrown open to the public, and the medical profession is cordially invited to attend and to participate in the discussions.

CAPTURE OF THIEVES THROUGH FINGER PRINTS. — Two thieves have been cleverly captured, through their finger prints, by the detective force of the city. On the afternoon of election day, Nov. 8, a residence on West Tenth Street was entered and a number of articles stolen from it. It was found that finger markings on the glass face of a clock in the house corresponded with the finger prints on file with the police as belonging to two men whose photographs were in the Rogues' Gallery. The two were on a list kept of known thieves who make a business of visiting houses whose owners are away, and this knowledge eventually led to the capture of these thieves.

CHOLERA ON AN INCOMING STEAMSHIP. — On the steamship *San Giorgio*, which arrived on Nov. 16 from Naples and Palermo, it was found that two persons in the steerage, a mother and her child of two years, had died and been buried at sea. While their deaths were described as due to gastro-enteritis, Health Officer Doty, after a preliminary bacterial examination of post-mortem evidence, became convinced that one if not both had died of cholera. There were also nine cases of illness in the ship's hospital, and these were taken to the Quarantine Hospital on Swinburne Island, while all the other steerage passengers were transferred to Hoffman Island for observation.

SCARCITY OF WATER. — Notwithstanding some recent rains, there is still great scarcity of water in Westchester County, and, under authority

granted by Mayor Gaynor and Water Commissioner Thompson, of New York, the Water Bureau of Yonkers began, on Nov. 16, the work of tapping the Croton Aqueduct at Ardsley, where the aqueduct runs parallel to the Sawmill River. For the present, a supply of between 3,000,000 and 4,000,000 gallons will be required from New York, and for this the city of Yonkers will have to pay about $500 a day.

Against Public Drinking Cups. — The State Health Department is co-operating with the railroads in endeavoring to do away with the public drinking-cup on trains and in stations, and in a recent circular states that there is no excuse for such on the train, or anywhere else, now that penny-in-the-slot machines serve out paper cups, and that metal collapsible cups can be purchased for a dime. The circular also warns the public against the use of the common towel, which at times may prove even more dangerous than the common cup, as the friction accompanying the use of the towel can easily rub disease germs from one face or hand into the eyes or a scratch in the skin of another person.

Profit Still in the Drug Business. — There would seem to be some profit still in the drug business. It is announced that the corner store at Thirty-fourth Street of the new Greely Square Hotel, which is to occupy the entire easterly side of Broadway between Thirty-third and Thirty-fourth streets, has been leased from the plans to the United Drug Company of Boston for a term of twenty-one years at the enormous rate of $110,000 a year. The store will contain about 5,500 square feet, so that the renting value averages $2 per square foot. This is said to be virtually double the price that has been asked for high-class ground floor stores in the choicest retail districts of Thirty-fourth Street and Fifth Avenue.

Endowment Fund, American National Red Cross Society. — President Taft having appointed committees in all the important cities of the country for the purpose of raising an endowment fund for the American National Red Cross Society, designed to represent a contribution of ten cents from each individual of the population, the New York committee has been very successful in securing a large amount in a short space of time. The subscriptions already aggregate $329,500, and those of $25,000 or over are the following: Mrs. E. H. Harriman and Mrs. Russell Sage, each $50,000; D. O. Mills (bequest), Jacob H. Schiff, Cleveland H. Dodge and Arthur C. James, each $25,000. The committee consists of H. P. Davison (chairman), Robert Bacon, Charles Hallam Keep and Lloyd C. Griscom.

Care of Tuberculous Patients. — At a meeting of the subcommittee on charities of the Commission on Congestion of the Population in New York, held on Nov. 15, M. J. Borden, secretary to Commissioner Drummond, of the Department of Public Charities, declared that the facilities for caring for tuberculosis patients in the city are entirely inadequate. "The daily population of our public hospitals and institutions," he said, "is about 10,000. The waiting list for admission to the tuberculosis pavilions is over 500. In 1902 there were only about 100 patients in these pavilions, but to-day they number over 800, crowded into space suitable for only about 500, and there are more than 30,000 people in the city suffering from tuberculosis. As long as the present tenement-house conditions continue, the city will be compelled to spend increasing amounts of money each year for the care of tuberculosis patients."

Mayor Gaynor and St. Mary's Hospital, Hoboken. — At a meeting of prominent men held on Nov. 11, a movement was started to raise a fund, by voluntary subscriptions from citizens of New York, to be presented to the sisters of St. Mary's Hospital, in Hoboken, as a Thanksgiving offering. The testimonial is to be given as a token of the gratitude and appreciation of the citizens for the sisters' great kindness to Mayor Gaynor and careful solicitude for his welfare when he was confined in the hospital after he was shot by James Gallagher. At the meeting a committee was appointed to take charge of this work, of which John D. Crimmins is chairman and A. Barton Hepburn, president of the Chamber of Commerce, treasurer. St. Mary's receives 4,000 patients annually, the great majority of whom are treated gratuitously, and there are at present over 300 patients in the hospital. Its work is much hampered and restricted by reason of the lack of necessary funds. The old building is in such poor condition that all but one floor is about to be vacated, and on the new addition to the hospital there is a debt amounting to nearly $150,000. No charge whatever was made for service in the case of Mayor Gaynor, but on leaving he presented the Mother Superior with a check, the amount of which has never become known.

6. LYDSTON, G. F. *A Case of Death under Gas and Oxygen Anesthesia.*

2. Louria writes an exhaustive paper on the value of lumbar puncture in diagnosis and treatment. Outside of its use in meningitis, this procedure has an important place in therapeutics as a means of relief for the meningismus of acute infections, the cerebral manifestations of uremia and the headaches of chlorosis; also in eclampsia, traumatic myelitis, concussion of the brain and meningeal syphilis.

4. Richards reports some peculiar results of eyestrain. He has been able to relieve a surprising variety of disorders — somnolence, insomnia, post-nasal catarrh, hoarseness, asthma, indigestion — by the correction of refractive errors. [L. D. C.]

4. Fordyce reports thirty cases of syphilis in which he has used Ehrlich's amido-arseno-benzol. He is impressed with the remarkable action of the drug in early cases and in cases resistant to mercury and iodide. The preparation and mode of administration are very important factors in successful treatment. The order of effectiveness is as follows: (1) Intravenous injection of a very dilute alkaline solution; (2) intramuscular injection of an alkaline solution; (3) acid solution; (4) neutral emulsion (intramuscular or subcutaneous). Primary lesions should be treated as early as possible; as an aid to complete sterilization, energetic local treatment should be employed — excision, cauterization or other means of destruction. In disease of the central nervous system the dose must be small (0.2 to 0.4 gm.). [L. D. C.]

2. Hatcher and Bailey, from experimental and clinical observation with the various digitalis products, state that the intravenous injection of crystalline onabain affords the most exact dosage possible in digitalis therapy and the most rapid effect. The effect of any digitalis body on the cardiac action is more prompt after intravenous injection than in any other way.

5. Stone claims that typhoid carriers, injected within a comparatively short time after their infection, probably receive more benefit from properly prepared autogenous vaccine than from any other known form of treatment.

"Contact carriers," who never to their knowledge have had typhoid, are more susceptible to inoculation than carriers who have had a definite attack of the disease. When the infection has persisted for years it may be difficult to clear up the condition by bacterial inoculations.

8. Rosenow states that evidence points strongly to the fact that injections of dead bacteria in acute endocarditis are of very small therapeutic value and may be actually harmful. [E. H. R.]

7. HEWLETT, R. T. *The Treatment of Cholera Asiatica with an Anti-endotoxic Serum.*
8. HARDING, H. W. *The Action of Chlorine upon Water Containing the Cholera Vibrio.*

3. McDonagh has found much larger doses of "606" needed to cure an early chancre than to cure an extensive gummatous ulceration, and concludes that the cure, therefore, is largely due to the amount of antitoxin formed. If a mother after giving birth to a syphilitic infant be treated with "606" while nursing the child, the child's symptoms quickly disappear, although no arsenic is present in the breast milk; therefore it must be due to the antitoxins formed by the death of spirochetes in the mother. He uses a nearly neutral solution of about 6 ccm. and injects between the scapula and the spine. There is occasional difficulty in breathing, owing to spasm of the chest muscles after this injection; this, however, soon passes off. As a prophylactic the drug is powerless, but in no primary stage treated with "606" did any secondary symptom develop. In the second stage, symptoms generally disappear after a single injection of 0.5 to 0.6 gr. Three cases of tabes with marked ataxia did not improve, and in general in the parasyphilitic affections, "606" is rarely, though occasionally, of use. [J. B. H.]

8. Although the causes of air embolism during labor are numerous, the most common one is the delivery of the patient under anesthesia in the left semi-prone position and failure to turn her over on her back as soon as the child's head is born. The left position tends to allow an inrush of air into the uterine cavity, which does not occur if the patient is on her back. Prophylaxis simply consists in placing the patient on her back. The symptoms, if not at once fatal, resemble those of embolism from a clot — spasmodic inspiratory attempts, convulsions, cyanosis, increased pulse, only they soon disappear, only to reappear again in a short while in worse degree than before. When such embolism has occurred, the placenta should at once be removed and the uterus washed out. Saline infusions, strychnine, digitalis and oxygen should be administered. Rest in bed for five to six weeks should be insisted on. The writer cites two interesting cases in detail.

12. Herff strongly recommends treating such degrees of contracted pelvis as will allow of it by means of induced premature labor. Especially if the life of the mother is more valued than that of the child is this operation desirable, as the mortality in the mother is practically zero, the after-effects almost none and the danger to the child only slightly greater than that other method which he advises, Cæsarean section.

20. Savage, Shuttleworth, Jones, Russell, *et al.*, discuss briefly the question of marriage and various mental disorders and degrees of insanity. Savage emphasizes the fact that in no case should marriage be allowed as a means or a hope of cure, especially in cases of so-called moral perversion, alcoholics, etc. [J. B. H.]

1. Keith gives an interesting study of diaphragmatic hernia. In his series the proportion of congenital to acquired cases is 26: 8. He describes the various forms and the anatomy of such herniæ.

2. Armstrong discusses typhoid perforation as it has occurred at the Montreal General Hospital. Out of 2,051 cases of typhoid, from 1897 to 1910, there were 93 cases, 4.5% of perforation. The author has studied 97 cases of perforation; 78 were operated on, with 24 recoveries, a percentage of 30.7%. During the past year, owing to earlier diagnosis and operation, in 19 operations 9 recovered, a percentage of 47.3%. In 50 out of 93 cases, the perforation occurred in very severe types of fever, while in 6 cases it was in the ambulatory type. He believes in using local anesthesia whenever possible. [J. B. H.]

1. The writer advances the theory that the hemolytic substance which has been found in the gastric contents of patients having carcinoma of the stomach is a free fatty acid coming from the tumor itself. He has tested for hemolytic properties the contents obtained after an Ewald meal in a large number of cases of carcinoma, benign gastric disturbances and normal cases. The evidence seems to show that the hemolytic substance cannot come from the meal. Before testing the stomach was always washed clean so that food previously ingested did not interfere. Tests were also made for bile and intestinal ferments which have hemolytic properties. It was found that in cases of gastrectasis the test was unreliable, but when there was no regurgitation through the pylorus a positive result occurred in the great majority of cases of proven carcinoma and a negative result in most of the non-malignant conditions. (The fact that of thirteen doubtful cases only three reacted positively suggests that the test may be of less value in the early stage of carcinoma.)

7. Melchior calls attention to the danger of serious incontinence following forcible dilatation of the anal sphincter. He says that this can be entirely avoided by doing the work under complete anesthesia and by not using great force.

8. It is stated that persons working with ascaris worms in the fresh stage frequently suffer from poisoning in the form of conjunctivitis or swelling of the hands, and the writer believes that these are due to an emanation from the parasite. He thinks it probable that the symptoms observed in ascaritis are due to the same poison, but he does not give definite information as to its nature. [G. C. S.]

1. Schreiber reports having injected 325 patients intravenously with "606." He has observed a rise of temperature within a few hours after the injection in a considerable number of them. It lasts as a rule only a short time. A few patients had nausea, vomiting or diarrhea and one had urticaria. No other ill-effects were noted and in no case were the symptoms severe. It is the writer's impression that results were more prompt and surer by the intravenous than by other methods of injection and he, therefore, recommends it for syphilis of the central nervous system. He insists on small dosage when the drug is used intravenously.

2. The writers report on 30 cases of syphilis treated with "606." Ten of these received it intramuscularly and 20 subcutaneously. They are in favor of the subcutaneous method on the ground that absorption is better and quicker, that infiltration occurs less often and that the slight pain it causes is more easily borne in the back than in the buttock.

3. This article contains so much of value that a complete summary cannot be given here. Three hundred and seventy-five cases of syphilis of all sorts and stages were treated with "606." Of these, 44 were followed for five months, and 8 of them had recurrence. The following indications are given for the use of "606": Malignant syphilis; syphilis in any stage when mercury is not well borne; cases of recurrence after repeated mercurial treatment; cases of syphilis in the early incubation period (when possible also excision of the chancre or destruction of it by the Holländer hot-air method); tuberculous syphilis; visceral syphilis; decrepit patients; latent syphilis when the Wassermann reaction persists; and parasyphilitic affections in the very early stage.

Contra-indications: Severe non-syphilitic retinal or optic nerve diseases; severe organic disease of heart or vessels; severe pulmonary disease except tuberculosis;

advanced degeneration of the central nervous system; and, temporarily, cases of angina or febrile diseases. The latter can be injected after the acute illness has passed. Remarkable results were obtained in malignant syphilis. [G. C. S.]

12. Hartmann. *Supervision of Infants.*

1. The writer has been successful in diagnosing ulcer of the stomach by means of the x-ray. He gives diagrams and reports a few cases. His conclusions are similar to those of Haudek, whose work he seems not to have seen. (Ref.: Münch. Med. Woch., July 26, 1910.) The method is chiefly of use for deep ulcers situated on the greater or lesser curvature, because it depends upon the shadow thrown laterally by the bismuth in the ulcer. He says that when an abnormal spot of bismuth (which he describes in detail) can be seen projecting from the stomach, and that when in addition an hour-glass constriction can be seen in the same region, then the diagnosis of a deep ulcer can be made with certainty and its position can be stated.

2. Grosser reports three cases of sudden death in infants, in all of which hemorrhages were found in the parathyroid glands. He believes that destruction of these glands by hemorrhage was the cause of death, and he urges that in all similar cases the parathyroid glands should be carefully studied.

3. Greven says that when mercurial treatment is combined with the use of "606" the excretion of arsenic in the urine seems to be delayed, and that when iodide of potash is given, excretion of arsenic is apparently delayed.

6. Lattes reaches the conclusion that an increase of the fat in the blood, contrary to Reichers, diminishes the quantity of chloroform necessary for narcosis, and that this results because the fat-tissue of the body takes up much less chloroform. [G. C. S.]

5. The author goes into the different pathological conditions to which the semen is disposed. He emphasizes the importance of using fresh material uncontaminated. He also shows that it is not an easy thing to make a positive diagnosis of male sterility. He considers that the male is the responsible factor in very many cases of sterilitas matrimonii, but emphasizes the fact that an examination should be made by a specialist before the patient accepts the diagnosis of male sterility as final, and even then a gynecologist should make certain that all is normal with the wife. 1. Nicolle and Mauceaux have made an exhaustive study of oriental pustule. They find that the causative agent is the Leishmania tropica, which they have been able to reproduce on artificial media, and which is similar to the protozoa of kala azar. The cultures grow best at 22° C. and will live at this temperature for two months. Transplantations are best made on the tenth to fifteenth day. The virus of the oriental pustule is pathogenic for man, monkey and dog. Successful inoculation experiments have been carried on. They describe in brief the characteristics of the lesions, but have put aside their histologic study for another special work.

This virus is inactive in the horse, cat, sheep, white rat, goat and donkey. Also, it is inactive when given intraperitoneally in a variety of animals. The point for favorable inoculation is on the nose and eyebrows especially. An immunity against a second inoculation is obtained provided that the first attack has entirely healed. During the first attack further infection may occur. There is probably a negative phase of hypersensibility. Kala azar infection when cured offers an immunity against the pustule disease. The latter offers increased resistance but not immunity to kala azar. The dog is suspected of being the common carrier of this infection. [C. F., Jr.]

Miscellany.

CHOLERA IN VARIOUS LOCALITIES.

During the week ending Nov. 19, there was a moderate recrudescence of Asiatic cholera in Italy. Thirty-five new cases and 9 deaths of the disease were reported, as against 13 cases and 5 deaths the preceding week. A fresh outbreak of cholera is reported from Constantinople, where, on Nov. 17, there are said to have been 37 new cases and 18 deaths, and on Nov. 18, 49 new cases. The steamer, *San Giorgio*, which reached New York City on Nov. 16, from Naples and Palermo, was held at quarantine on account of the death of 2 passengers, during the voyage, with symptoms suggestive of cholera. Nine other passengers, all from the steerage, were

found to be sick with similar symptoms, and were detained on suspicion for diagnosis. On Nov. 17, another suspected case of cholera was detained at Quebec, Canada, by order of the United States immigration physician stationed at that port. The patient, a Russian, who arrived at Quebec, on board the *Royal George*, from Bristol, England, was destined for Oronto, Wis. The vessel on which he sailed has been quarantined. It is gratifying to observe such evidences of the vigilance and zeal with which the extensive frontiers of our country are guarded by United States officials against invasion by this disease.

DESIRABILITY OF A STATE PSYCHOPATHIC HOSPITAL.

The desirability of establishing a state psychopatic hospital or sanatorium for the observation and study, during temporary detention, of borderline psychoses and of patients in the incipient stages of mental alienation is still under consideration by a special commission, consisting John B. Tivnan, of Salem, chairman; Dr. William N. Bullard, of Boston, secretary; Dr. Burnham R. Benner, of Lowell; Hon. Edward S. Bradford, of Springfield; and Charles E. Ware, of Fitchburg. At a hearing in the State House last week before this commission, Dr. Henry R. Stedman, of Brookline, chairman of the board of trustees of the Taunton State Hospital, pointed out some of the disadvantages of such an institution, and its possibilities of conflict with the work of the Psychopathic Hospital for the Metropolitan District, soon to be completed. On the whole, however, he approved of the establishment of the proposed hospital, by the state, on a small scale and as an experiment. Other opinions, favorable and adverse to the project, were expressed by other physicians present at the hearing.

Correspondence.

PARIS LETTER.

Recent Developments in the Syphilis Question.

[From Our Special Correspondent.]

Paris, Oct. 31, 1910.

Mr. Editor: The syphilis question has been making rapid strides of late. What with the discovery of the germ of the complaint, of the possibility of reproducing the disorder in animals, of the Wassermann reaction and of the apparently specific action of various forms of arsenic on the vitality of the germ, the study of this disease has advanced more during the last few years than during as many centuries previous to the finding of the spirochete pallida.

But all of these steps in advance do not stand on the same footing in the eyes of the public, at least over here. The germ, the transmission of the disorder to the higher apes, and the Wassermann reaction were looked on with eyes of indifference, — more or less as matters of scientific interest alone, concerning no one outside of the profession. A temporary ripple of excitement occurred when Brieux carried the subject on to the public stage in his well-known play that every one went to see, and coined his now-famous name for the disease, "avarie" (i. e., damage; adjective, damaged). This term filled a deeply-felt want. In spite of the liberty with which we treat all subjects here, both in conversation and press, the crude word syphilis stuck in people's throats, and few papers would have ventured to print it. But with this harmless little term "damaged, all barriers were removed, and Madame X. now tells Mlle. Y. in a public salon and in ordinary tones that Mr. Z. is *avarié*, without a moment's hesitation.

Another ripple of interest was created among the public when an enterprising physician, together with a well-known firm, succeeded in reproducing biological pictures of the spirochete pallida, together with numerous other germs, and gave cinematographic representations of the same to public audiences. I was present at one of these demonstrations, and I must confess that it was one of the emotions of my life to see these germs thrown on a screen, some of them *as large as a man's forearm*, and wriggling and squirming around among cells, blood corpuscles, intestinal detritus, etc., just as they act when placed fresh under a microscope. It was positively *overpowering;* and the feeling crept over me, in spite of myself, that it was a wonder any one of us was alive to tell the tale if such ferocious enemies as these were abroad in the land. There was one series of pictures of the blood of a patient with some rare tropical disease whose name escapes me, taken on successive days, and showing the progressive multiplications of the germs among the blood corpuscles until the latter were entirely swamped by the former and the blood was turned into a grovelling mass not unlike a heap of maggots, that was simply terrifying!

But these little ripples of interest were the merest bagatelles as compared with what has occurred since Ehrlich came forward with his 606. The other discoveries, if mentioned at all in the daily, political press, had at most the honors of three lines in fine print among the *faits divers*. But 606 was received with the honors of war and full regimentals, the editors feeling that here was a guest to whom too much courtesy could not be shown, as any one of them might have need of him when least expected. For we here transpose the common dictum about tuberculosis and say that every man either has been, is or will become *avarié*.

The result was that the daily press, *Matin* at the head, fell on the question like one man, and the front page and leading columns, in the widest and biggest type, have been freely used in disseminating news about Ehrlich and his famous 606 until really we are a bit sick of it. Furthermore, this campaign afforded an opportunity for more or less questionable efforts on the part of enterprising practitioners to keep or bring their physiognomies and merits before the public gaze. The irrepressible Doyen was the first to seize the chance, and opened fire in his usual place, the first column of the first page of the *Matin*, in an article more or less critical concerning Ehrlich and the new preparation, which I think he must now regret having written, since it amounts practically to the fact that his gun went off, to use Kipling's expression, "slightly prematoor." He also took the occasion to again call attention to the merits of his mycolysin, which somehow or other continues to be ignored, nor can I make out that, in the eighteen months or so since this remedy was put on the markets, the city death-rate among the infectious disorders (which the preparation was announced as destined to put an end to once and for all time) has shown any noticeable diminution.

Another confrère, Mouneyrat, also took advantage of the discussion to call public attention to a preparation of his called hectine, which he says is far preferable to 606 and has, he claims, been already tried in sixty thousand cases, — I say *sixty thousand!* I do not know this confrère, but it seems to me that for a preparation of which the general medical public has never heard to have been already tried on that number of patients without its fame being noised abroad strikes me as singular. The French have a very neat expression for emergencies like this: "*Cela n'est pas possible; ca se serait su!*" This series of *s's* is delightful. However, I was both surprised and chagrined to see no less a personage than Bouchard take part, in an interview, in this discussion in the daily press, and refer to the merits of hectine; so I suppose there must be something in the story. But how Mouneyrat, in a short

space of time, can have collected a series of cases of that magnitude passes my comprehension. Is everybody in the country in the active phase of syphilis? This claim of Mouneyrat has furthermore given rise to what appears to be rather an unpleasant incident. It seems that Ehrlich claims that Mouneyrat did not discover hectine at all, but got the idea from him himself during a visit to the Frankfurt laboratories. Hence, talk of lawsuits, patent infringements, etc. In short, a disagreeable affair.

Well, then, as I said, for the past three months, since early August, the daily papers have been filled with articles about Ehrlich, visits to his laboratory, interviews with this man and that man, the opinions of so-and-so of the Institut Pasteur, discussions before the Academy of Medicine, telegrams from Ehrlich denying things that were said before that learned body, — until the public mind has come to think of nothing else but syphilis, and even children in short clothes are treating their dolls with this 606, which they see at the head of articles in all the papers, for this mysterious disease which I suppose they look on as some kind of measles or whooping cough special for grown-ups.

The result of all this has been rather surprising and unexpected, and was described to me by the head of one of the laboratories here where they prepare the serums, remedies put up in bulb form, and other hypodermic preparations that are in such common use in Paris. He said that any number of old syphititics, whose disease had been quiescent for years so that they had practically forgotten all about it, had become uneasy on reading so much about syphilis in the papers; and that many of them had begun to treat themselves with hypodermics of soluble preparations of mercury, while the most advanced section, the up-to-daters, were applying to him in such numbers for a Wassermann test, to see whether their disease was in an aggressive or quiescent stage, that he had been obliged to create a special department for the Wassermann test and put a man at the head of it ($10 a test!). As to his sale of bulbs of mercury, it had quadrupled!

So much for the gossip on this subject, — now for more serious details.

The remedy was, I believe, first used clinically in March last. Since that time the question of the treatment of syphilis by 606 has been up before three or four German congresses, while the German medical press has teemed with articles on the subject. An amiable Frenchman, who signs J. D. in the *Presse Médicale*, has been kind enough to wade through and assimilate the more important portion of this dreary German prose, on behalf of his confrères, and has obligingly produced a digest of the subject in the number of Oct. 19. While referring those who wish for fuller data to the article itself, where they are exposed with the neatness and lucidity in which the good French writer excels, I will take the liberty of stealing a little of this man's thunder and send you the salient facts of the article.

Opinions are practically unanimous as to the efficacy of the drug, whose action appears to be little less than miraculous in certain cases, — curiously enough, the particularly grave ones. But the enthusiasm of the first hour has had time to calm down, and 606 is no longer looked on as the harmless preparation that was going to cure any case of syphilis in one single injection. Those who have had opportunity to use the remedy on a large scale, while admitting its really great qualities, say that we are still altogether in the experimental stage with this preparation, and that a great deal has yet to be learned about it. Furthermore, it has already given rise to some nasty accidents, and its effect on sight has been claimed by some to be similar to that of atoxyl, though this has been vigorously denied by Ehrlich. However this may be, it is certain that the German physicians in whose hands the remedy has been placed have been very cautious in having the patients' sight thoroughly tested before applying the treatment. That the remedy is still in its experimental stage is perhaps best shown by the fact that its users do not even agree yet as to dose and technic, each man apparently having a different way of preparing the substance for injection, whether hypodermic or intravenous. The latter method is painless, but in the early days the preparation used for hypodermic administration was extremely painful, preventing the patient from walking or assuming a seated position, and necessitating even in certain cases confinement to bed for a week. In this particular undoubted progress has been effected, as methods of dissolving the powder, which is very delicate and comes in little bottles in which a vacuum has been created, have been devised that permit of hip-injections being made without any pain whatever.

The dose to be given at a séance has also not yet been accurately determined. Ehrlich advises 0.45 to 0.50 for women; 0.50 to 0.60 for men. Alt, however, claims that it is preferable not to exceed the dose of 0.50, as above that figure the patient is exposed to accidents such as tachycardia, irregular heart action, syncope and nausea. Other experimenters, again, appear to have used larger doses, and 0.70 and 0.80 have been freely administered, — even as much as 1.20! Wechselmann, on the other hand, does not advise the single dose, but accords his preference to the small dose frequently repeated.

The most remarkable features of the result of the treatment by 606 in the primary and secondary stages are: First, its marvelous effect on the mucous patch, the infecting element *par excellence* of the disease; and, second, the fact that in a few days it does away with cervical leucodermia, a symptom which mercury does not affect in the slightest degree. The practical importance of the action of 606 on the mucous patch will escape no one's attention. If by means of a single injection (now painless) a patient can be prevented with almost certainty from transmitting the disease to others, we have acquired a means of treatment whereby in dispensary and hospital out-patient departments the large category of men and women who have neither time, education nor intelligence sufficient to insure a proper treatment by mercury being carried out can be rendered quite innocuous to the community at large in a very short space of time. The result of the method must unquestionably be a rapid diminution in the number of fresh cases within a very short period.

But the triumph of this new remedy appears to be in the ulcerous forms of tertiary syphilis and in early malignant syphilis, — just where we most needed it, as many of these cases either resist mercury altogether or yield to its action in a very slow manner. As the writer says: "It seems as though the deeper and more destructive the lesion, the quicker the cicatrization; the greater the resistance shown to mercury and iodism, the more brilliant the results from 606." In many cases of visceral syphilis its effect is equally satisfactory, and in particular many ocular forms can be treated in this way with most encouraging results. Syphilis of the nervous system is still a debateable ground. Ehrlich does not cease to advise caution where there is organic trouble of the central nervous system; in fact, he would apparently prefer that at least for the present the remedy should not be used with this category of patients at all. Some physicians, however, have passed over this warning and have published results that have been satisfactory. Possibly the unsatisfactory ones have not been brought into prominence! At any rate, there is considerable talk about a certain number of cases treated by 606 that have ended fatally.

The question of heredo-syphilis, before and after birth, is treated in this excellent review, as also that of its action on the spirochetæ themselves and on the Wassermann test. Several instances have been reported where, on the other hand, 606 failed to act altogether. There are already many cases of relapse after treatment, so that the vision at one time held before our eyes of the cure of the disease by a single injection will have to be relegated to the repository of lost illusions. The article finally treats of the accidents, light and serious, due to the treatment, and of the cases of death following it that have been published. My space, however, is limited and I must be satisfied with referring the reader to this painstaking and up-to-date review of the question.

The general impression resulting from the perusal of this article is that a valuable step in advance has been made, but that the millenium is not yet at hand. Our therapeutics of syphilis have been modified, but not revolutionized; the death knell of mercury and iodide is not yet ringing. To me really the most important side to the entire question, if experience bear out its accuracy (14,000 cases have been treated now, according to the latest statistics I have seen), is that mentioned above: its rapid curative action on the infectious element of syphilis, the mucous patch. "*S.*"

RECORD OF MORTALITY

CHANGES IN THE MEDICAL CORPS U. S. NAVY DURING THE WEEK ENDING NOV. 19, 1910.

SHOOK, F. M., passed assistant surgeon. Detached from the Naval Medical School, Washington, D. C., and ordered to duty at the Naval Hospital, New York, N. Y. Nov. 12, 1910.

SOCIETY NOTICES.

THE NORFOLK DISTRICT MEDICAL SOCIETY.— A regular meeting of the Society will be held at Masonic Temple, 171 Warren St., Roxbury, Tuesday, Nov. 29, at 8 o'clock. Telephone, Roxbury 22753. Business; Communication: "The Use of Obstetric Forceps in Posterior Positions of the Occiput," Edward P. Starbird, M.D. Discussion opened by Frederick L. Good, M.D. Refreshments after the meeting.

BRADFORD KENT, M.D., *Secretary*,
798 Blue Hill Ave., Dorchester.

NEW ENGLAND BRANCH OF THE AMERICAN UROLOGICAL ASSOCIATION.— There will be a meeting of the New England Branch of the American Urological Association at the Boston Medical Library on Tuesday, Nov. 29, at 8.15 P.M. Program: (1) Demonstration of patients. Reports of cases. Demonstration of specimens and instruments. (2) Papers on tumors of the bladder: (*a*) "Pathology and Prognosis," Dr. Wm. F. Whitney. (*b*) "Some Clinical Aspects Based on a Series of Personal Cases," Dr. Lincoln Davis. (*c*) "The Transperitoneal and Suprapubic Operations," Dr. C. L. Scudder. (*d*) "The Intravesical Operations," Dr. Horace Binney. Discussion.

R. F. O'NEIL, M.D., *Secretary*,
379 Beacon St., Boston.

NEW ENGLAND ASSOCIATION FOR THE EDUCATION OF NURSES.— The fall meeting of the New England Association for the Education of Nurses will be held in the John Ware Hall of the Medical Library Building, 8 Fenway, Boston, Mass., on Wednesday, Nov. 30, at eight o'clock in the evening. The topic of the meeting will be "The New Registration Law; What It Means and Its Advantages." The members of the Massachusetts State Board of Registration will be the speakers of the evening. The public is cordially invited to attend and take part in the discussion.

RECENT DEATHS.

DR. FRANK N. LEWIS, who died on Nov. 13 in New York City, was born in 1857 at Burlington, Vt. He was an academic and medical alumnus of the University of Vermont. After serving as an interne at the Mary Fletcher Hospital, Burlington, Vt., at the Brooklyn Eye and Ear Hospital, and at the New York Eye and Ear Infirmary, he settled in practise in New York City in 1888. He became instructor in ophthalmology at the New York Post-Graduate Medical School, and was visiting surgeon and later executive surgeon at the Manhattan Eye, Ear, and Throat Hospital. He was a member of the American Medical Association, of the New York State Medical Society, of the New York Academy of Medicine, of the American Ophthalmological Society, and of the New York Ophthalmological Society. He is survived by his widow.

DR. JAMES ROSS WAGGENER, who died at Brookline, Mass., on Nov. 17, was born in Kentucky in 1846. On Sept. 12, 1872, he entered the United States Navy, in which he became medical director, and on Jan. 20, 1903, was commissioned captain. Since his retirement on May 6, 1907, he had lived in Brookline.

DR. PLACIDO FERRATI, who died in Worcester, Mass., on Nov. 16, had practised medicine in that city since 1905. He graduated from the Tufts Medical School, Boston, in 1902.

DR. DANIEL WAYLAND JONES, who died in Boston on Nov. 18, was born at Ashburnham, Mass., on Jan. 14, 1829. He received the degree of M.D. from the University of New York in 1852, and for ten years thereafter practised medicine in Medfield, Mass. He then went to Philadelphia for a time, and in 1871 and 1872 traveled and studied in Europe. On his return he at first settled in Newton, Mass., where he served for a time as city physician. In 1878 he came to Boston, where he continued in practise until his retirement in 1894. During his later years he had made a specialty of diseases of the rectum. He was a member of the American Medical Association, The Massachusetts Medical Society, and the Massachusetts Medical Benevolent Society. He was a widower.

DR. THEODORE R. BURGTORF, a well-known physician of the Borough of the Bronx, New York City, was shot and killed by his wife as he lay sleeping beside her early in the morning on Nov. 14. Mrs. Burgtorf then shot herself twice in the abdomen, and is in the Fordham Hospital, with some chance of recovery, it is stated. She admitted the shooting, saying that she was crazed by pain, which she could endure no longer, and was prompted by a desire not to leave her husband behind. For a long time she had been suffering from tic douloureux, and some three years ago, in a paroxysm of pain, she attempted to kill herself and her son. Three months ago she underwent an operation, and it had been thought that she was improving. Dr. Burgtorf was fifty-five years old and a native of Germany. He was graduated from the Long Island College Hospital, Brooklyn, in 1894, and was very successful in practise. He is survived by one son, Adolph, twenty-four years of age, a graduate of the New York College of Dentistry.

THE DOCTRINE OF VITALISM IN MEDICINE.*

BY M. G. SEELIG, M.D.,
Assistant Professor of Surgical Pathology in St. Louis University.

BETWEEN living and non-living matter there is the fundamental difference that in living matter there is always something else present in addition to the properties found in non-living bodies. This additional "something" endows living bodies with a "tendency to disturb existing equilibria, to reverse the dissipative processes which prevail throughout the inanimate world, to store and build up where they are ever scattering and pulling down; the tendency to conserve individual existence against antagonistic forces, to grow, and to progress, not inertly taking the easier way, but seemingly striving for the best, retaining every vantage secured and working for new ones." This quotation from Professor Ward's, "Naturalism and Agnosticism" serves excellently the twofold purpose of defining life and of emphasizing the "something additional," which, for want of better understanding, we call "vital force." Vitalism concerns itself solely with the abstract thought that there is inherently resident in living matter, a directing element or force that is not under the control of the known laws of physics or chemistry. Vitalism is the *testimonium paupertatis* of the scientist, his credo expressed in terms of honest agnosticism.

Antipodal to this doctrine of the inscrutability of the fundamental basis of life stands the dogma of the non-vitalist: that since many of the phenomena of life conform with the laws underlying the properties and actions of inorganic bodies, we have every reason to assume that the sum total of activities constituting life is as much subject to the laws of chemistry and physics as is the sum total of activities of gunpowder or of the threshing machine. According to this view the human body is a machine, not only in the sense that its activities are directed towards a purposeful end, but also in that each step towards the accomplishment of this end is predicated upon a definite axiom. The sum total of these axioms constitutes the great body of natural law. There are, says the non-vitalist, many axioms still in the crucible of proof, many still unguessed; but the result of the final assay will invariably be the disclosure of a principle as essentially mechanical, physical or chemical as are the already established laws of the inorganic world. The assumption of an intangible, immeasurable vital force is, according to the doctrine, unnecessary and, to say the least, uninspiring.

To attempt to set a measure of comparative value on these two doctrines of vitalism and mechanism would inevitably lead us on to the treacherously thin ice of metaphysical argumentation. Our interests, I take it, are primarily medico-historical, and out of respect to those limited interests, the moot points of static and dynamic teleology, abstract causality, things in themselves, perception, the ego and consciousness must be left tenderly in trust with the philosopher and psychologist. This sacrifice to the needs of medical history should not be made, however, without full consciousness that the trust funds are valuable assets, subject to claim on demand. If justification be required for such brusque and autocratic refusal to incorporate philosophy with history, it can be offered in an exceptionally concrete fashion. This small pamphlet of nineteen pages by Prof. A. Bier, entitled "Ueber die Berechtigung des Teleologischen Denkens in der Praktischen Medizin," represents a philosophical defense of associating the phenomena of disease with the idea of purposefulness; the redness, pain, swelling and heat characterizing inflammation are all expressive of nature's purpose to overcome the disease. Bier characterizes this type reasoning as teleologic and emphasizes a professed unwillingness to camp with the vitalists and their mixed company of "unklaren Köpfe und Mystiker." This large volume of three hundred and fifty pages by Dr. Thoele, of Hannover, written in answer to Bier, not only charges him with being tautological, mystical and unscientific, but actually refers these charges to the fact that he has reasoned faultily on a vitalistic basis. Our justification, then, for dismissing philosophy must rest largely on the same basis as Osler's reason for avoiding "thorny theological questions," namely, the layman's natural desire to seek shelter under the wing of authority. While the authorities are settling their terms, indulging in their polemics and establishing their compromises, the medical historian may exercise his uncommon privilege of surveying the arguments without specifically entering them.

Let the survey begin with Aristotle — surely an appropriate start; for Aristotle occupies the position of an apostle both in matters medical and philosophical. His two important works, "The History of Animals" and "Concerning the Soul" served to establish a medico-philosophical autocracy of thought that held sway down through the Middle Ages. Many of his fundamental conceptions in anatomy and physiology, we know, are incorrect, but the basis of his reasoning is eminently sound. "It demands most careful examination," he says, "to determine in just what fashion an animal or plant develops from seed; for surely everything that has occurred must occur from something, through something and as something; but after all, the important factor is not so much *out of what* the parts develop as *through what* [force] they develop." Driesch construes the Aristotelian doctrine regarding development in such fashion that the soul is made to vivify the semen, thus preparing it to coalesce properly with the female element. This is almost undefiled vitalism. There is much in Aristotle, despite Driesch, that forces one to recognize his appreciation of the similarity existing between ontogeny and human craft and art work; much, in other words, that labels him as a mechanist. The interpretation of what he

*Read before the Boston Society for Medical Improvement, Nov. 14, 1910.

says is often difficult and obscure, but whether Driesch be right or wrong in the construction he places upon Aristotle's doctrine of development, and whether it be permitted any one to assert dogmatically that Aristotle was or was not a vitalist, it is certainly true that the old philosopher, dissatisfied with the purely mechanical explanation of life, felt the inner impulse and necessity of wrestling with the question of the rationality of existence; he groped about for something higher than the purely mechanical, and, as a result of his groping, he laid down, in rather unclear fashion, it is true, a problem which Eucken, in his recent Noble prize essay, characterizes even to-day as "torturing and pressing in that what we held a sure possession now becomes an object of weary search."

In reality, Aristotle occupied a middle position between the pure idealism, pantheism if you please, of Thrales, Empedocles and Plato, and the materialistic mechanistic doctrine of Democritus. He enjoyed the privilege, however, of working in a more clarified atmosphere than these, his predecessors, for Hippocrates before him had firmly established the essential difference between the organic and inorganic worlds. The Hippocratic doctrine of pneuma is important, not only because it is the earliest medical explanation of the basis of life, but also because, appropriated as it was by Galen, it maintained authority as a doctrine for fifteen centuries. This idea of pneuma as promulgated by Hippocrates is such an inextricable snarl of possibilities as to defy unraveling. To one it appeals as a material something comparable to oxygen; to another as an impalpable, intangible, sole-animating substance, theoretically essential to an understanding of life processes; and, accordingly as one construes it, he is mechanist or vitalist. From an historical point of view, this alone is significant: that, following Aristotle in succession, the Alexandrian schools of medicine and the school of methodists represented by the Asclepiadists, added not one whit, not even by way of subtlety, to the views of Hippocrates and Aristotle. Likewise, when Greek medicine was transplanted on Roman soil, and reinvigorated by Galen, nothing essential was added to the former doctrines concerning the vital principle of life. Galen's classification of pneuma or spiritus into "animal spirits," "vital spirits," and "natural spirits," with their subordinate "attractive," "propulsive," "retentive" and "secretive" faculties, adds nothing either new or practical, serving merely to emphasize again the inevitable groping for light, the restless search for a final cause.

After Galen — the deluge. Roman medicine declined, Rome fell, and the interregnum of intellectual darkness set in. Mysticism, superstition, folly, loose thinking, mad-cap doctrines and insane dogmas were the orders of the days. In the general tottering and fall, medicine crumbled with the rest. The Middle Ages knew no vitalism, no mechanism, no nothing; for all these years the field of thought lay fallow. In course of time, however, the fallow field began to bear fruit as fallow fields always will. The renaissance was inaugurated by Columbus, Gutenberg, Copernicus and Luther, during the fifteenth and early sixteenth centuries. Medicine mirrors the reawakening during the sixteenth century in such names as Vesalius, Fallopius, Servetus, Eustachius and Paré, and in such facts as the founding of ophthalmology, and the laying claim to botany and chemistry as subservient to medicine. With the announcement of Harvey's discovery, medicine emerged from the period of renaissance and started on a route of advance which, for directness of course was never before equalled. From now on, practically every name of historical significance in medicine stands for an individual who both promulgated a new scientific theory or fact and concerned himself in some fashion with the doctrine of vitalism, either by way of disclaiming or asserting belief in vital force as a ruling element in the organic world.

Before entering farther in the chronological discussion of the medical history of vitalism, it will be of more than passing interest to note just how the problem assumed an importance so great as to protract a discussion for three centuries. There is a German word which characterizes the swing and authority of a movement of thought as a "tendenz." Such a tendenz, whether it manifest itself in the arts or in the natural sciences, is almost invariably the outcome of the preestablishment of a philosophic doctrine; for it is as impossible to restrict the influence of an Aristotle, a Kant, Nietzsche or Spencer to the domain of pure philosophy as it is to limit the laws of gravity to falling apples. Let us, for example, consider Bacon and Descartes, the two men who did most to revolutionize philosophical thought in the seventeenth century. In reality, these two philosophers did not work simultaneously, — Descartes superseded Bacon, — but their combined effort resulted in the establishment of the doctrine that all natural phenomena are made up of scales of facts, the more complex ones resting for their explanation upon the simpler ones, but all of them governed by primary laws. Bacon enthroned doubt, Descartes consecrated it, and then each proceeded to the development of his own system. Bacon's system was in itself a machine, — an organum, — constructed so as to enable the mind to overcome obstacles, to open vistas, to riddle seemingly unsolvable problems. He pointed out the supreme importance of observation and induction as the essential elements in the final solution of primary laws. His insistence was upon verification. Descartes, in his turn, strove to apply to the human body mathematical theorems similar to those used in reaching his famous conclusions concerning light refraction. Underlying his mathematics and his philosophy was the fundamental proposition that the human body is a machine. And so, Descartes and Bacon were instrumental in setting in motion a tendenz that colors medical theories to-day even more deeply than three centuries ago.

Beyond all question of doubt, the establishment

by Descartes and Bacon of the doctrine of primary governing laws in nature did much to correlate the phenomena of the human body with activities of the inorganic world, activities brilliantly studied at this very time by Galileo and Newton. In so far as this correlation holds true, medicine, in common with the philosophy of the time, must be regarded as mechanistic in tendency. The iatrochemical and iatrophysical schools, developed during this period under Sylvius, Willis, Sydenham, Santorini, Baglivi, Bellini and others, mirror most clearly the tendency of the times to reason along lines of pure materialism. But just as in the philosophy of Descartes the machine teaching had a counterpoise in the shape of an extra-corporeal force, — the God element, — and just as in the system of Bacon, with all its rigid adherence to the observation of natural law and order, there was nevertheless a hearkening to the idea of "divine inspiration," so, too, in the medicine of these times, the doctrine of pure mechanics was opposed by a dogma more spiritual in tone. Van Helmont, for example, impressed medicine deeply with his theory of Archeus — an extracorporeal force practically unlimited in its regulative powers. If exception be taken to the introduction of Van Helmont's views, on the ground that they were so saturated with piety and mysticism as to be valueless, we still shall not have to travel far afield in order to deduce that medicine was not wholly mechanistic in her trend. William Harvey, in his epoch-making discovery, demonstrated in a fashion never since excelled, the fundamental interdependence of body function and the laws of mechanics. One cannot avoid the conclusion, however, that Harvey's belief was firm in the existence of a force above pure mechanics, a "something over" after mechanics have accounted for everything probable. In his "Exercitationes de Generatione Animalium" he states that the developing fetus is a natural body, animated, however, by a soul; it is the product not of the uterus, but of the soul (*non opus uteri sed opus animae*). The development of the human body is the work of an "opifex," and is the result of the existence in the germ of a "principium," which, for the want of a better term may be called "primordium vegetabile," "and he," says Harvey, "who unqualifiedly correlates the body with the idea of a machine, is not a proper judge [*aequus aestimator*] of nature." On the basis of such excerpts as these, Driesch classifies Harvey as an "unbefangener Vitalist."

During the eighteenth century, medicine, in common with the other sciences, underwent a general process of clarification. The philosophy of Locke, Voltaire, La Mettrie and Leibnitz furnished the necessary thought stimulus to awaken the labors of such men as Bernoulli, Galvani, Volta, Priestly, Lavoisier, Linnæus and Buffon. The reaction in academic medicine was furnished by Albrecht von Haller, Valsalva, Albinus, Camper and Winslow, and in practical medicine chiefly by the famous trio of systematizers, — Hoffmann, Stahl and Boerhaave. Bernoulli, for the pure scientists; Haller, for the biologists, and Boerhaave, for the practical medical men, referred the phenomena of life back to "spiritus animales"; Stahl, the father of "animismus," located the regulation of all organic activity in "anima," the ultimate principle of life. Probably the most interesting feature of this era is the evident tendency to unravel the problems of organic life by brilliant experimentation, to construe phenomena as forces, and yet, withal, to recognize the existence of a higher force (spiritus animalis, phlogiston, anima), whose very definition was impossible. Dismiss from consideration these attempts to interpret the final principle, and the era is one of mechanistic activity; concentrate on the thought devoted to explaining the essence of life and we are dealing with vitalists striving to interpret the ultimate. It is little short of fascinating to contemplate the confusion of thought and the activity of strife that went hand in hand with Leeuwenhoek's studies of spermatozoa, Swammerdam's and Malpighi's embryological studies and the work of Reaumur and Spallanzani on regeneration. Bound up in the arguments regarding evolution and epigenesis, and in the theories of the ovulists and animalculists, there is the ever-present confusion due to ignorance of final causes combined with an almost insatiable desire for "more light." Naturally studies of this sort, approaching as they do scientific bed rock, compel one to declare either for or against the existence of a vital inherent formative force. If he accepts the existence of such a force his task is comparatively simple, consisting merely in a declaration of belief such as Casper Wolf makes in his *vis essentialis*. If, on the other hand, he denies the existence of such a force, he must either "stack arms" or else conceal his uncertainty in a confused terminology such as that used by Weismann in his elaboration of biophores and determinants.

If space permitted, it would be interesting from a purely historical point of view to survey the actual systems of medicine that owed their origin in large part to this eighteenth century discussion of vital force; to show, for example, how Cullen, Brown, and, through Brown, our own Benjamin Rush, Sauvages, Rasori and Glisson worked under the direct stimulus of the immediately preceding age; but the detailed study of system must give way to the larger purpose of tracing the influence of vitalism through the later period of medical history. Indeed, it is scarcely to the point to consider Blumenbach, who, toward the end of the eighteenth century, summed up the entire subject in two small monographs, thus earning for himself the distinction of placing the doctrine of vitalism on a basis of scientific rationalism. The important consideration is this: that during the discussion that began with Harvey early in the seventeenth century and ended with Blumenbach late in the eighteenth century, medicine was making steady continuous progress. An inventory shows, as gains to medicine, the circulation of the blood, the development of embryology, the

demonstration of bacteria, the birth of histopathology, the rational beginning of physiology and a tremendous advance in the systematic study and development of anatomy and clinical medicine. On the other side, philosophy may claim the expansion of Harvey's original idea of vital principle or "primordium vegetale" into Blumenbach's conception of irritability, contractility, sensibility and nisus formativus (*bildungstrieb*) as four coequal representatives of vital force. If we be granted the privilege, for argument's sake, of assuming that Blumenbach's quartet clarified the philosophic atmosphere, we can even then only say that while the atmosphere was clarifying, medicine was thundering ahead.

Indeed, nothing illustrates more clearly the inherent tendency of practical and scientific medicine to establish its own equilibrium, to set its own independent pace of advancement, than the fact that steadiness was secured and advance accomplished during this era, side by side with the promulgation of Kant's doctrines regarding judgment and pure reason, and Schelling's and Hegel's views on "Natural Philosophy." Baas states that if Kant's views regarding the admission only of mathematical reasoning in medicine had gained more influence, the science would have been reduced to a maze of theory. As regards Schelling and Hegel, it suffices to say that their philosophy has been made responsible for such possibilities in medicine as mesmerism, homeopathy and rademacherism. It is difficult to determine whether Schelling and Hegel were expounders of a rational or of a mystic vitalism, and whether Kant was vitalist or not. It is certain, however, that Humboldt, Liebig, Von Baer, Johannes Mueller, Schwann, Schleiden, DuBois Reymond, Helmholtz and Claude Bernard were some of the men who worked under the influence but not under the spell of the new natural philosophy. It is equally certain that Humboldt, Liebig, Van Baer and Mueller were champions of vitalism, and that Schwann, Schleiden, Reymond, Helmholtz and Bernard were champions of the machine theory of life. "Lebensrichtung," "lebensreiz," "primum movens," "vitalen eigenschaften" are some of the terms culled from Liebig, Von Baer and Mueller, indicating more clearly than could a lengthy discussion the complexion of their belief in an underlying vital force.

The middle era of the nineteenth century furnished two epoch-making discoveries that rudely upset the philosophical, or perhaps better said, the metaphysical basis on which the vitalism of these men rested. Following the enunciation of Robert Mayer's doctrine of the conservation of energy, and Charles Darwin's theory of natural selection and adaptation, medical thought became even more emphatically mechanistic in tone than during the old days of the iatromechanical and iatrochemical schools. Helmholtz dealt sledge-hammer blows to any doctrine that controverted pure mechanics as a sufficient and all-satisfying explanation of vital processes, and, curiously enough, he based his reasoning on the premise that Mayer's doctrine of conservation of energy established the identity of organic and inorganic forces, leaving no room or place for a purely speculative vital force. Schleiden's and Schwann's discoveries regarding cell life tended, naturally, to strengthen the belief in the power of experiment and study eventually to furnish all the details of a complicated living machine. DuBois Reymond, in his classical and now famous *Ignorabimus* dissertation, further strengthened the materialistic trend first by an avowed *ignoramus* regarding many knotty problems in science, an emphatic *ignorabimus* regarding the possibility of ever explaining the power of thought, and a clear enunciation of his belief that the resort to vital force was futile, because "force" is merely a measure and never a cause. Claude Bernard threw all the weight of his authority against the admission of vitalism in science or medicine, in his "Leçons sur les Phénomènes de la Vie." "What is this tremendously powerful force," he asks, with some heat, "which can accomplish nothing, acting alone?" Against such onslaughts as these, even by the admission of so ardent a vitalist as Driesch, the light of vitalism flickered out! At this stage of medical history it was that there developed the "deadly hatred of philosophy," an era represented by the old Vienna school, a group of men to whom an individual represented a conglomerate mass of functionating organs, and whose absorbing interest was the post-mortem verification and explanation of disturbed function. No philosophy, no speculation, precious little therapy, — just the working out of laws!

Such an attitude of mind is apt to prove and, indeed, did prove to be a bit unsatisfying. All that was necessary to stimulate the spirit of unrest was admissions by such men as His, Goette and Baer for the embryologists, that rational morphology was not to be explained entirely on a purely mechanical basis; the statement by Bunge for the physiologists that, although the theory of mechanics may in time prove satisfactory, just now it is not sufficient to meet the demands, and, finally, the stand taken by Virchow, for the pathologists, that from the purely practical, as contrasted with the scholastic and metaphysical point of view, "sind wir auch in der Pathologie vitalisten." Virchow stated bluntly that he felt compelled to believe that the essential basis of life is a force that must be differentiated from the molecular force of the inorganic world. If such a belief should seem to reflect upon him as a man of science, he could only answer in the words of Chauffard, "Peu d'anatomie pathologique éloigne du vitalisme, beaucoup d'anatomie pathologique y ramene."

It was this new swing of authority that re-established vitalism on the fairly firm basis that it maintains to-day, and it seems that the strength of the vitalistic argument is mirrored by the reflected light from names of prominence in the world of science. Thoele, for example, has been able to classify many of the later-day medical men of prominence into groups of vitalists, each

group representing a medical specialty: Pflueger, Weigert, Verworn, Rubner, Ribbert as the group of physiologists and pathologists; Roux as the head and master of the group of embryologists, with Hertwig as coadjutor; Ehrlich, Buchner, Pirquet and others as representing the bacteriologists, and Goldschneider, Edinger and Bier for the clinicians.

But what shall we say to the fact that among these names, despite the assurance of Thoele, there are men who vehemently disclaim vitalistic allegiance? Our answer must be the statement already furnished, that our object merely is to trace consecutively the influence upon and dominance in medicine of thoughts relating to final principles and causes. To attempt to do more than this would mean entering the lists of what Virchow very properly called a *Wortstreit*. Cull over the very small part of the literature on vitalism mentioned this evening, and you will find no less than a score of substitute terms to take the place of the expression "vital force"; each substitute is clothed with its own specific and connotative qualifications, which must, of necessity, be conceded, if orderly and conclusive argumentation is to result, but which, as a matter of fact, are never conceded by any two parties to the argument. It is truly difficult to determine who is vitalist and who not; indeed, there is more than a pale haze of obscurity enveloping the very fundamental terms of mechanism and vitalism. How natural to expect, therefore, that even among the vitalists themselves there should be contending schools. Strecker and Pauly as disciples of the type of vitalism laid down by Bunge stand out in rather sharp contrast to such vitalists as Driesch, Reinke and Schneider — a contrast that has been softened rather than explained away by the work of Uexkuell, of the present-day Heidelberg school of vitalists. Uexkuell's volume came off the press late in 1909. It leaves the problem very much as it found it.

How unsatisfactory a survey of this sort is, no one realizes better than he who makes it, particularly if he makes it with the futile purpose of reaching a final definite conclusion. Satisfaction must come to the medical man solely through the consciousness of having gained an intimate acquaintanceship with the details of a problem, perplexing, it is true, unsolved, and yet, withal, intimately bound up with the advance of his own particular brance of science. Those of us who feel the inner impulse to unravel the complex phenomena of disease are confronted constantly with the ultimate unknowable. However we may construe this ultimate principle, — either as a molecular force or as a force eternally beyond the ken of man, — no one may cavil at our belief, provided we do not allow it to paralyze our efforts.

The danger for science that lurks in vitalism is the tendency to supplant belief in an incomprehensible force by worship of that force. For some of us, the very idea "unknowable" carries with it enough of the mystic to "put my reason to St. Paul's sanctuary. Who can speak of eternity without a solesism or think thereof without an extasie?" ("Religio Medici.") The danger that lurks in the mechanistic doctrine, as has been stated by our own William James, is that "it is essentially a view of things from the outside and knows nothing of how they happen." Vitalism furnishes a ready-made answer to an all-perplexing question. Mechanism suggests, by analogy to the inorganic world, a method of solving perplexities; but, as Taine has pointed out, the method means the creation of a faith by every individual, for himself, thus subjecting himself to every curiosity and to every pain.

What more natural, with William James in our mind, than that those of us who are floundering in doubt should reach out towards a practical system of thought that measures the problem for us by its utility, and emphasizes the spirit of compromise by teaching that truth at any particular time is only provisional and likely to be converted into other forms of truth? For me, just such a compromise is furnished by the Italian philosopher Rignano, when he states that "whether one clearly recognizes it or not, it is just this search for the nature of the vital principle which properly constitutes the principal object and final goal of all biologic study in general." With this definite goal in view, with the application of proper, orderly and logical methods of investigation, it becomes immaterial whether we constitute ourselves a Charles Gradgrind, "a man of realities, a man of facts and calculations. A man who proceeds upon the principle that two and two are four, and nothing over, and who is not to be talked into allowing for anything over. With a rule and a pair of scales and the multiplication table always in his pocket, sir, ready to weigh and measure any parcel of human nature, and tell you exactly what it comes to," — or whether we believe with Burton that it is merely necessary to

> "Grant an idea, primal cause, the causing cause, why crave for more?
> Why strive its depth and breadth to mete, to trace its work, its aid to implore,
> Unknown, incomprehensible, whate'er you choose to call it, call;
> But leave it vague as airy space, dark in its darkness mystical."

PRESENT KNOWLEDGE OF THE LAWS OF HEREDITY.*

BY W. P. GRAVES, M.D., BOSTON.

GERMINAL CONTINUITY.

The laws of heredity generally accepted at the present day are based fundamentally on the theory of germinal continuity. This theory divides the cells of multicellular organisms into two classes called the *somatic* cells and the *germ* cells. The somatic cells constitute all the differentiated cells which make up the structure and

* Read before the Bigelow Club, Oct. 12, 1910.
Although many authorities have been consulted in the preparation of this paper, the writer is chiefly indebted to Prof. J. A. Thompson, whose writings on heredity are especially clear and illuminating to the beginner.

various organs of the body. They have only a temporary existence and become disintegrated on the death of the organism. The other class of cells, namely, the germ cells, are the reproductive cells and are represented by ova in the female and spermatozoa in the male. These cells, or the substance which constitutes them, remain undifferentiated throughout the life of the organism. Each one of them carries condensed in its nucleus all the heritable qualities derived through the parent ovum from preceding generations, and under the stimulus of fertilization is capable of passing this inheritance on to succeeding generations. Thus the germ cells possess potentially the quality of immortality. The theory of germinal continuity has been based on facts observed in the development of certain lower organisms. Boveri has shown that the fertilized ovum of the thread worm of the horse divides into two cells, one of which becomes the *parent of all the somatic cells*, and the other becomes the *parent of all the germ cells*. Similar observations have been made in a number of worms and insects. In most cases, however, this distinct separation of the somatic and germ cells at the first division cannot be recognized, and a morphological continuity of the germ cells from ovum to ovum cannot be followed. In order to fill in this gap in our knowledge as to the exact nature of the germ cells in most organisms between birth and maturation, Professor Weismann, the most distinguished of modern evolutionists, has devised the hypothesis of the *germ-plasm*, and his views are at present generally accepted. Weismann's theory may be summarized as follows.

(1) In each development, a portion of the specific germ plasma which the parent ovum contains is not used up in the formation of the offspring, but is reserved unchanged for the formation of the germinal cells of the following generations.

(2) What is actually continuous is the germ plasm " of definite chemical and special molecular constitution." A continuity of germinal cells is now rare; a continuity of intact germinal plasma is constant.

(3) This germ plasm has its seat in the nucleus, is extremely complex in structure, but has nevertheless an extreme power of persistence and enormous powers of growth.

(4) The germ substance proper must be looked for in the chromatin of the nucleus of the germ cell.

(5) The splitting up of the substance of the ovum into a somatic part, which directs the development of the individual, and a propagative part, which reaches the germ cells and there remains inactive, constitutes the theory of the continuity of the germ plasm. (From J. A. Thompson's " Heredity.")

Thus the germ cells form a distinct continuous lineage entirely apart from the somatic cells, and are not to be regarded in any sense as having been produced by the somatic cells. The parent, therefore, whose individuality represents a collection of mortal somatic cells, is not in a strict sense the producer of his offspring, but only the temporary custodian of a portion of the immortal germ plasm. " The animal body is in reality a vehicle for ova, and after the life of the parent has become potentially renewed in the offspring, the body remains as a cast-off envelope whose future is but to die." (Sir Michael Foster.)

Noll eloquently writes: " The vital capacity of the cells of the functioning permanent tissue is always limited in time. Without limit, on the contrary, and never finding a natural close, the vital power of the germ plasm is preserved. This substance does not age. It produces new passing individuals, but it is permanently preserved in their progeny; it is always productive, always growing young and increasing. Thousands upon thousands of generations which have arisen in the course of millions of years were its products, but it lives on in the youngest generations with the power of giving origin to coming millions. The individual organism is transient, but its germ plasm, which produces the immortal tissue, preserves itself imperishable, everlasting and constant." [1]

A graphic conception of the theory of germinal continuity can best be given by Wilson's familiar diagram (Fig. 1).

PHYSICAL BASIS FOR THE LAWS OF HEREDITY.

It has long been known that the new individual results from the union of only two germ cells, namely, the ovum of the female and the spermatozoon of the male, but the nature and organization of these germ cells is a matter of comparatively recent knowledge and one of surpassing interest. It is not within the scope of this paper to review the different modes of reproduction, namely, the budding, division and sporulation of unicellular organisms, nor, in multicellular organisms, the rare cases of true hermaphroditism and parthenogenesis. We can refer here only to sexual reproduction, viz., the union of two germ cells of opposite sexes, so-called amphimixis. The ovum is a sphere of comparatively large size containing living matter which is called cytoplasm, together with a certain amount of nutritive material. It contains a central kernel or nucleus which is a network of delicate threads carrying minute masses of stainable material which is called the chromatin. This chromatin under certain forms of activity separates into definite

[1] In this quotation the expression " germ-plasm " has been substituted for " embryonic substance " which occurs in the original.

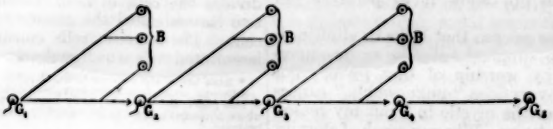

FIG. 1.

small rod-like masses which are called chromosomes. All the cells in the body of a given individual contain exactly the same number of chromosomes, and every individual of a given species possesses the same number of chromosomes in his cells.

The spermatozoon is much smaller than the ovum, and its size may be less than one millionth of the egg of the corresponding species, the egg under such circumstances being swollen with nutritive material. Most of the cytoplasm of the spermatozoon resides in the tail, the function of which is purely one of locomotion. The nucleus is situated in the head and usually contains exactly the same number of chromosomes as does the corresponding ovum. While the ovum is passive, the spermatozoon is active and motile.

As will be shown later, all the characters of inheritance probably reside in the chromosomes, and it is, therefore, to a study of these remarkable bodies that we must turn in order to have a clear understanding of the laws of inheritance. As has just been said, every species of plant or animal has a fixed and characteristic number of chromosomes "which regularly recur in the division of all of these cells; and in all forms arising by sexual reproduction the number is even." (Wilson.) For example, sharks have thirty-six chromosomes; the mouse, salamander, trout and lily have twenty-four; the ox, guinea pig, man and the onion have sixteen. The even number of chromosomes is due to the derivation of one half the number from each parent. In 1883 Van Baneben made the remarkable discovery that the nuclei of the ripe ovum and spermatozoon contained each one half the number of chromosomes characteristic of the body cells. It has also been discovered that this reduction in the number of chromosomes takes place two generations before the formation of the definitive germ cells. This process is termed the *maturation* of the germ cells, and it is by this means that the number of chromosomes in a given species is kept constant.

The actual process of amphimixis, or the union of the ovum and the spermatozoon, and the future development by division of the ovum is too complicated a one to be described in this paper. It may briefly be said, however, that after the spermatozoon has bored its way into the ovum, the surrounding membrane becomes thickened and prevents the entrance of other spermatozoa. The chromosomes in the nuclei of the two united cells then split longitudinally, and the fragments from each cell pair off equally in opposite poles of the ovum in such a way that, when the daughter cells are formed by the division of the ovum, each daughter cell receives an exactly equal contribution from its paternal and maternal chromatic substance. Inasmuch, therefore, as the chromatic substance contains all the heritable qualities, it follows that the new individual receives an exactly equal inheritance from both his father and mother.

PROOF THAT THE NUCLEUS IS THE BEARER OF HERITABLE CHARACTERS.

It is generally accepted that the nucleus and not the cytoplasm of the germ cell transmits the heritable qualities of the individual. Arguments for this view are that the nuclear elements divide with an exact equality, while the cytoplasm does not; the important phenomenon of maturation takes place in the nucleus and not in the cytoplasm; the spermatozoon contains only a relatively small amount of cytoplasm, which is almost completely used up in the formation of its organ of locomotion; the ovum, on the other hand, contains a relatively large amount of cytoplasm, which apparently is used as nourishment during the early stages of development of the new individual.

Extraordinary experiments in artificial fertilization strongly corroborate this theory. Boveri dissected out the nucleus from the ovum of a sea-urchin. He then fertilized the enucleated ovum with the normal spermatozoon of another species. The offspring from this union resembled only its father.

Delage divided a sea-urchin's egg into two parts, one of which contained the nucleus. These two parts, together with a complete normal egg, were then allowed to be fertilized by spermatozoa of the same species. The normal ovum developed into a normal sea-urchin; the portion of the dissected ovum which contained the nucleus developed into a normal sea-urchin of smaller size; the portion of the dissected ovum without a nucleus developed, but incompletely. This experiment showed that fertilization can take place with only one nucleus, but that the full quota of cytoplasm is necessary for complete normal development. Loeb has caused the eggs of sea-urchins to develop parthenogenetically by changing the chemical composition of the sea water. In other words, he caused the sea-urchin eggs to grow without fertilization by a spermatozoon, the converse, therefore, of the experiments of Boveri and Delage.

These experiments show that there must be at least one nucleus present to cause development, and also that the nucleus of each germ cell, both male and female, contains all the elements for the production of a perfect individual of the species. They also go to show that the liberating stimulus which gives rise to the unfolding of a new individual is, in reality, a chemical reaction.

HEREDITY AND VARIATION.

The facts of heredity and evolution depend both on the tendency in species of like to beget like, and also on the tendency of species to continual variation. In complex organisms, although the offspring always bears a general resemblance to its parent, the two are never exactly alike. This tendency of the offspring to deviate from its parent forms the basis of evolution. The tendency to resemblance in type is termed the "inertia of species," and may be illustrated in the human species by the persistence of woolly hair in the negro, the slanting eyes of orientals, the oval face of the Eskimo or the characteristic nose of the Jews. Many animals have lived on unchanged for many millions of years. For example, the bony structure of the Lingula of to-day is exactly like the fossils of the Silurian ages.

The science of heredity is chiefly interested in the modes and character of changes in type which occur in species. These changes are divided into two important classes, referable to the two classes of cells into which the organism is divided, i. e., the somatic cells and the germ cells. Those changes which affect the somatic cells are termed *modifications*, and those changes which take place in the germ cells are called *inborn variations*. This classification is of extreme importance in the understanding and practical application of the laws of heredity, and for that reason it is necessary to give special attention to its consideration.

MODIFICATIONS.

From the day of its actual birth, i. e., the division of the fertilized mother ovum, the new being is in a state of continual adjustment to a complex environment. The organism possesses a normal amount of elasticity, and, after ordinary adjustment, as Thompson well puts it, "like a bow unstrung rebounds to its previous state." Examples of such adjustment and rebound are the disappearance of sunburn after a summer vacation, the recovery from the effects of heat or cold or infectious diseases, etc.

In other cases, however, the environmental adjustments create a permanent structural change in the soma of the individual. In other words, "the limit of organic elasticity has been transcended," and the bow unstrung no longer rebounds to its previous state, but remains permanently warped. These permanent structural changes are termed *modifications*, or, more familiarly, *acquired characters*. Examples of modifications are the deforming of trees by the wind; the permanent tanning of the skin of soldiers in the tropics; occupation deformities; the small feet of Chinese women; immunity after contracting certain infectious diseases; the blacksmith's biceps, etc. The great importance of the consideration of modifications or acquired characters lies in the problem as to whether such modifications may be transmitted by heredity.

INBORN VARIATIONS.

In contrast with modifications which have to do only with the somatic cells, inborn variations have their origin purely in the germ cells. In other words, inborn variations include all differences in hereditary resemblance after all modifications have been subtracted. Examples of inborn variations are albinism in the negro; the appearance of extra digits, as in double-pawed cats; the long manes and tails of wonder horses. As to the transmissibility by inheritance of inborn variations there is no question.

To the evolutionist and biologist the analysis and study of inborn variations is of extreme importance, but the discussion of them can in this paper be only briefly alluded to.

Variations are divided into two classes, termed continuous variations or fluctuations, and discontinuous variations or mutations.

CONTINUOUS VARIATIONS OF FLUCTUATIONS.

Fluctuations are those small variations or deviations from type which occur frequently in every generation. They "amplify or lessen existing qualities without really changing their nature. They always oscillate around an average, and if removed from this for a time they show a tendency to return to it. They are inadequate to make a single step along the great lines of evolution, whether progressively or retrogressively; they do not form the raw material of evolution, as has often been supposed."

Most of the variations which we are accustomed to observe in man and the higher animals are of the fluctuating variety. The deviations from parental resemblance which we observe in our children, such as differences in height, mental acumen, athletic facility, appreciation of or indifference to music or literature, are all fluctuating variations. Deviations observable in our domestic animals which are so important to the breeder, such as speed in a horse, the shape of a dog's tail, special qualities of excellence in cows, hens, pigs, etc., are examples of fluctuating variations. By careful and rigorous artificial selection new types of species may be maintained so long as there is no slackening in the selection. As soon, however, as the selection is slackened the type reverts speedily to the average mean of the species. Darwin believed that new species were created by the natural selection of fluctuating variations, a process which, if true, would involve an enormous amount of time. Most modern biologists admit the possibility of some species having been evolved in this way, but the remarkable discoveries of Mendel and De Vries of the laws of inheritance in plants have, for the most part, completely changed the view of zoölogists with regard to the origin of species in this way, and the generally accepted opinion now is that most species have sprung into being by sudden bounds rather than by the slow creeping process of natural selection. The changes in such cases are supposed to be the result of what are called *discontinuous variations*, or variations which appear suddenly without any observable continuity with previous deviations.

DISCONTINUOUS VARIATIONS: OR MUTATIONS.

Variations of this kind were considered by Darwin and then rejected. The application of the theory of discontinuous variations to heredity forms the basis of the differences between the modern school of evolution and that of Darwin. Discontinuous variations have been named by DeVries, *mutations*, and it is important to become familiar with this term and its significance, as it appears constantly in all modern literature of heredity. It may be said that they occur rarely as compared with fluctuations, which are constant in every generation. They follow no law of frequency, although it is probable in some species that there may be a periodic tendency to mutations. "They lead by a bound to a new position of organic equilibrium; they breed true to this

position, and there is no regression to the old mean." DeVries and his school maintain that all species have originated by mutation instead of by the continuous selection of fluctuations. It should, however, be remembered that DeVries is a botanist, and that all deductions concerning mutations have been taken from the study of plants. With regard to mutations in animals, comparatively little is known. Probably such instances as the tailless cats of the Isle of Man, certain breeds of hornless cattle, short-legged lambs, thornless roses, giants, wonder horses, white negroes, are examples of mutations. Apparently mutations may or may not breed true to type.

TELEGONY AND MATERNAL IMPRESSIONS.

Telegony relates to the popular belief long held by breeders that an hereditary influence of one sire may be exercised on the future offspring of the same mother paired with a different sire. Darwin was a believer in this phenomenon, and cited as a proof the celebrated case of Lord Morton's mare. This mare, a pure-bred Arabian, was paired with a quagga, as a result of which a hybrid was produced. Later the mare was paired with a pure-blooded Arabian stallion and produced two colts with striped markings on the legs and neck. It has long been the belief among breeders of dogs, and apparently not without reason, that a purebred bitch, if accidentally crossed by a dog of another breed, is spoiled for future pure breeding. There are numerous interesting examples recorded of telegony, although it has been shown that very few of them will stand the test of a rigorous scientific cross-examination. The following is an example.

A man of striking physical beauty and marked regularity of physiognomy, blond in type, with blue eyes, had an amorous episode with a young woman of dark complexion. Later the young woman married a man of dark complexion and with unusual irregularity of features. A child was born, which resembled in an extraordinary degree, both in features and in coloring and in other ways, the mother's former lover.

The general belief among investigators of to-day is that there is probably no well-founded scientific basis of truth in telegony.

The popular belief in maternal impressions is extraordinarily prevalent even at the present day. Although striking instances not infrequently occur of birth-marks, deformities, etc., which bear a peculiar resemblance to some powerful impression made on the mother's mind during pregnancy, it is difficult to conceive that there could be any mental influence on the part of the mother which would affect the anatomical structure of the *foetus in utero*, when it is considered that there is absolutely no nerve connection between the mother and the fetus. Probably all cases of so-called maternal impressions are coincidences.

TRANSMISSION OF ACQUIRED CHARACTERS.

We have seen in an earlier portion of this paper that acquired characters are based on permanent modifications in the makeup of an individual, which have been brought about by the external influences of his environment, and that they are entirely independent of those inborn characters which he has received as an inheritance from the germ-plasm of his parents. It can readily be seen that by far the most important question in the study of heredity is whether acquired characters are transmissible to future generations. The solution of this problem is of moment not only to the biologist, but also to the individual himself in his personal, social and national relations. Herbert Spencer expressed the importance of the question when he said: "Considering the width and depth of the effects which the acceptance or non-acceptance of one or the other of these hypotheses [transmissibility or non-transmissibility] must have on our events of life, the question, Which of them is true? demands beyond all other questions whatever the attention of scientific men. A grave responsibility rests on biologists in respect of the general question, since wrong answers lead, among other effects, to wrong belief about social affairs, and to disastrous social actions."

The debate between those who do and those who do not believe in the transmission of acquired characters has been an interminable one since the time of Lamark, the first great authority to assert transmissibility. He believed that all inherited characters are acquired. Since his time Herbert Spencer has been the greatest champion of Lamarkianism, while Galton, Darwin, Weismann, Huxley and Wallace and most of the modern biologists have been for the most part disbelievers in transmissibility.

The arguments for and against the theory are extremely interesting, but are too numerous and complicated to be more than alluded to in this paper. It can only be said that the arguments against the theory are based largely on the fact that the germ cells, by which the inheritance is carried, remain undifferentiated and distinctly apart from the body cells during the life of the individual, and it is inconceivable that influences which affect only the body cells can be impressed in any way on the germ cells so as to reproduce in a succeeding generation the same particular somatic results.

Anatomical evidence against the theory of transmission is also strong. The practice of circumcision for many hundreds of years has made no difference in the anatomical structure of Jewish babies. Chinese babies are born with normal feet notwithstanding the modificational deformity to which their mothers have been subjected for centuries. No one believes that the removal of the vermiform appendix of every individual of the human race would have the slightest effect in producing an appendix-less species.

It is sufficient for the purposes of this paper to summarize the more common belief of modern evolutionists by saying that *no incontestible evidence has yet been produced that acquired characters may be transmitted.*

The non-transmissionists, if I may use the term, do, however, make one admission, which compels them at times to occupy a middle ground. They do not deny that the body is subject to certain modificational influences which may be of such a saturating character as to influence directly the germ cells so that they may produce defective offspring. An example of this kind may be seen in the mentally and physically defective children which chronic alcoholics are wont to produce. Other influences, such as lead poisoning, narcotism and possibly toxic effects of certain diseases, may affect the germ cells so as to produce variations in the offspring. It should be remembered in the consideration of this subject that changes which are brought about in the *foetus in utero*, such as deformities by constriction of the cord or infections from tuberculosis or syphilis through the placenta, must be regarded as modifications and not inherited qualities, because in a biological sense the individual is born at the time of the division of the fertilized ovum, and the fetus, having already started on its life cycle, is only a temporary parasite during its uterine sojourn.

Those who believe in the transmission of acquired characters are accustomed to cite as proof of their theory that pathogenic bacteria when subjected to certain degrees of heat for successive generations gradually lose their pathogenic power, and it is asserted that this diminution of virulence is inherited. The other school, however, points out that, as bacteria are unicellular organisms, there is no division into somatic and germ cells. Any environmental influence like heat saturates the entire organism and, therefore, directly injures the germinal substance. A case of this kind is analogous to the effect of alcohol and other saturating poisons which in complex organisms may so affect the germ-cells as to create variations in the offspring.

The non-transmissionists appear to admit that certain environmental nutritive influences, good or bad, to which the germ cells of an individual may be subjected act as a liberating stimulus to set going certain variations which might otherwise have remained latent.

Notwithstanding the general skepticism as to the transmission of acquired characters, the importance of nurture, education and environment must not be underrated. The individual with his raw material of inheritance is extraordinarily plastic. A common-place inheritance carefully nurtured may surpass an excellent inheritance with an indifferent education. The great jumper, Page, was born with weak legs, and in a concentrated effort to strengthen his muscles acquired the character or modification of being the world's greatest jumper. Sandow in his youth was feeble and weakly and acquired his extraordinary development as a pure modification. It is not likely that Page could transmit his saltatory ability, nor Sandow his muscular development, but it is undoubtedly true that both Page and Sandow inherited and could transmit, as an inborn variation, the mental power of concentration which enabled them to succeed so well in their physical training.

Thompson, in summarizing the importance of nurture and education, notwithstanding the impossibility of transmitting their results by inheritance, writes optimistically, "Unlike the beasts that perish, man has a lasting *external* heritage capable of endless modification for the better, the heritage of ideas and ideals embodied in prose and verse, in statue and painting, in cathedral and university, in tradition and above all in society itself."

HEREDITY IN DISEASE.

The fact that the science of heredity is still in its infancy, and that outside of plant life and the less complex forms of animal life practical facts are meager, is most appreciated when one studies what is known of heredity in diesase. This branch of the subject is the one which, of course, is the most vital to the interests of the physician. It seems evident that with the equipment of the rapidly accumulating knowledge which biologists are at present acquiring, the burden of increasing the knowledge of heredity in disease will rest in a large part upon the shoulders of those to whom is given the greatest opportunity for its study, namely, the clinicians and general medical practitioners. While the scientific investigator is studying in his laboratory the wonders of elementary life, the clinician may assist greatly in the solution of problems of heredity by the observation and collection of statistical data which appear almost daily in his professional experience.

From what is known of the subject to-day, it is evident that specific diseases are not directly inherited. It is equally evident that a predisposition to certain diseases may be definitely inherited, this predisposition being of the nature of a germinal variation. As will later be seen in the discussion of the Mendelian theory, heritable qualities may be either positive or negative, that is, an individual may inherit the absence of a quality. For example, the individual with pure blue eyes inherits the absence of some determinant, be it a ferment or what not, which causes the production of pigment in the iris. It may be imagined that an individual predisposed to a certain constitutional disease, as shown by the frequent occurrence of the same disease in his immediate ancestry, inherits the absence of a determinant which would create a resistance to this disease.

There is statistical evidence to show that there may be distinctly inherited predisposition to gout, rheumatism, asthma, cardiac disease, obesity, tuberculosis, insanity and other nervous affections. It is of great importance to determine always whether a certain disease occurs as an inherited germinal variation or whether it is purely adventitious, for on this point depends the question of the transmissibility of the disease. For example, deafness occurring as a germinal variation is transmissible; deafness occurring early in life as the result of accident or infectious disease is not transmissible. Imbecility or epilepsy occurring as inherited variations are transmissible, but if they are the result of a cerebral injury, they

are not transmissible. The following instance of a family residing in a neighboring town is instructive.

An imbecile father and an imbecile mother have seven imbecile children. The popular story in the town is that the father acquired his imbecility early in youth from being kicked in the head by a horse. Statistical evidence, however, makes it probable that the imbecility of the father was inherited and existed before his injury, because all the children are imbeciles and if he had been normal at birth a certain proportion of the children would be normal. This is substantiated by the fact that one of the imbecile daughters gave birth to three illegitimate children by normal fathers and all three of the children are normal and one of them is of exceptional aptitude.

Certain defects may be germinally inherited which are not diseases in the sense of being pathological processes, but which may, some of them, lead to disease. Such instances are hemophilia color blindness, freckling, diabetes insipidus, myopia, inability to digest the proteids of eggs or milk, etc. Anatomical defects may also be inherited germinally. Examples of this are albinism, absence of metacarpal bones, hare-lip, cervical fistulæ, spina bifida, tailless cats, hornless cattle, earless sheep, etc.; or the variations may be of the plus instead of the minus variety, as polydactylism. Monstrosities are less often due to germinal inheritance than to some injury in utero, as, for instance, from the pressure of an hydramnios or a strand of the amnion.

Microbic diseases, with the possible exception of syphilis, are not transmitted as such. Tubercle bacilli are not carried in the germ cells from either parent, even when the genital organs are infected with tuberculosis. It is true that in rare cases the *foetus in utero* may be infected from the mother through the placenta. Inheritance in the matter of tuberculosis is entirely the transmission of a predisposition to the disease, a predisposition which is intensely hereditary, over 35% of all cases having an immediate tubercular ancestry.

Professor Hamilton writes suggestively of heredity in tuberculosis: "Most likely the particular vulnerability resides in the epithelium, the protective coverings of the body being too little resistant, too easily stimulated by external agencies, and too readily penetrated by the parasite of the disease." That the tubercular predisposition bears some relation to the anatomical structure is borne out by certain physical characteristics frequently seen in the tubercular patient, e. g., very dark or very light hair, bushy eyebrows, long eyelashes, lanugo growth over the spine, narrowness of chest and tallness of stature.

The details of the transmission of syphilitic disease are too well known to be described here.

One of the most important instances with regard to heredity in the light of the present progress of medical science is the transmissibility of acquired immunity to infectious disease. Ehrlich has shown by experiments in rabbits that acquired immunity may pass through the placenta to the *foetus in utero*. Cases have been known where a mother during pregnancy contracted and recovered from smallpox and transmitted her immunity to the fetus. Such immunity is not, however, to be regarded as inherited. The acquired immunity, derived from antitoxins and serums, unfortunately appears only to affect the somatic cells and must be classed with acquired characters or somatic modifications as there is no evidence to show that immunity of this kind is transmissible. This seems to be only an added proof of the inexorable law of the non-transmissibility of acquired characters.

The comparative immunity which certain races gradually acquire to specified diseases is an important question in the study of heredity. Examples of this kind are the gradual diminution of virulence which scarlet fever and measles have shown in some of the European races, notably in Germany; the immunity of Englishmen to tuberculosis as compared with the American negroes; the slight effect which the use of opium has on the inhabitants of India, who have employed it for centuries, as compared with the more destructive effect which it has on the Chinese, who have used it for a shorter period of time, and the extremely destructive effect which it has when introduced into races who have never used it; the comparative immunity which English-speaking races possess toward alcoholism, as distinguished from the annihilating effects which it has when newly introduced into savage races like the American Indians.

This gradual diminution of virulence has been used as an argument to prove the transmissibility of acquired characters. It should, however, be recognized that many of these diseases do not endow their individual victims with immunity, but rather with greater susceptibility. Individuals who have been afflicted with tuberculosis or typhoid fever do not acquire immunity, and chronic indulgence in alcohol or opium does not establish immunity in an individual towards these poisons, but rather makes him more susceptible to a craving for them. If acquired characters of this kind were transmitted by inheritance, there would be an accumulative inheritance of susceptibility to such an extent that the race would eventually be annihilated. Undoubtedly the gradual acquisition of immunity in a race to a certain disease represents an example of the survival of the fittest. It can be shown that racial immunity to a specific disease is in direct proportion to the experience which the race has had with the disease, and it is supposed that the more susceptible element has gradually been sifted out.

The predisposition to disorders of the nervous system is extremely heritable. This is said to be due to the fact that the nervous organism is the most complex in the body and is, therefore, most easily thrown out of equilibrium. Hamilton interestingly gives as a reason for this susceptibility to disease variation that from an evolutionary standpoint the nervous system is the most recent equipment of the body, and he gives evidence to show that the more recently inherited organs are less stable in the matter of germinal

variability. A neurotic tendency may appear in the offspring in the same form by which it was expressed in the parent, or it may be expressed differently. For example, some specific form of acute neurosis may appear in the offspring merely as a general neurasthenia, or a deficiency of control, and conversely. The main point to be borne in mind is that the hereditary variation is distinctively a predisposition.

What is called the "inheritance of secondary effects" relates to hereditary changes, which result from direct injury to the germ cells, as, for example, poisoning from alcohol, opium, lead, hydrocyanic acid and nicotine. Examples of the secondary hereditary effects which may result from chronic alcoholism in the parents are insanity, criminality, debility, infantilism, imbecility, structural abnormalities and epilepsy. One record of eighty-three epileptic children showed that sixty were from drunken parents. Experiments of injecting alcohol into eggs have produced actual defects and abnormalities in the offspring. Unquestionably the predisposition to the craving for alcohol is a heritable quality.

LAW OF FILIAL REGRESSION.

This law relates to the general tendency which highly differentiated species always exhibit to gravitate toward an average mean. We see gifted parents producing common-place children and, on the other hand, unexpectedly gifted children born from under-average parents. Francis Galton studied this tendency to approximate to a mean and reduced his observations to a definite law which he called "Filial Regression." He investigated about one hundred and fifty families with special reference to stature, eye color, temperament, artistic faculty and some forms of disease, and showed statistical evidence to prove that there was in all these respects a constant tendency to regression toward mediocrity, e. g., an unusually tall parent would be likely to have a child less tall than himself, while an unusually short parent would have offspring less short than himself. To quote Galton, "The law of regression tells heavily against the full hereditary transmission of any gift. Only a few out of many children would be likely to differ from mediocrity so widely as their mid-parent, and still fewer would differ as widely as the more exceptional of the two parents. The more bountifully a parent is gifted by nature, the more rare will be his good furtune if he begets a son who will be as richly endowed as himself, and still more so if he has a son who is endowed yet more largely. But the law is even-handed; it levies an equal succession-tax on the transmission of badness as of goodness. If it discourages the extravagant hopes of a gifted parent that his children will inherit all his powers, it no less discountenances extravagant fears that they will inherit all his weakness and disease. It must be clearly understood that there is nothing in these statements to invalidate the general doctrine that the children of a gifted pair are much more likely to be gifted than the children of a mediocre pair. They merely express the fact that the ablest of all the children of a few gifted pairs are not likely to be as gifted as the ablest of all the children of a very great many mediocre pairs. Nor must the fact of regression be supposed to affect the general value of a good stock or the general disadvantage of a bad one. Two gifted members of a poor stock may be personally equivalent to two ordinary members of a good stock, but the children of the former will tend to regress; those of the latter will not."

THE LAW OF ANCESTRAL INHERITANCE.

If the law of germinal continuity is true, it must be assumed that in the germ plasm of every individual there are condensed the characteristics of a infinite number of ancestors. As Thompson puts it, "The individual inheritance is a mosaic of ancestral contributions." This idea is familiar to all in the frequently seen re-expression of characteristics which were conspicuous in a grandfather or great-grandfather. Galton, in order to make a generalization of this fact, studied the data as to stature and other qualities in man, and as to coat color in Basset hounds, and from these statistics he enunciated the following law, "The two parents between them contribute *on the average* one half of each inherited faculty, each of them contributing one quarter of it. The four grandparents contribute between them one quarter or each of them one sixteenth and so on, the sum of the series, $\frac{1}{2} + \frac{1}{4} + \frac{1}{8} + \frac{1}{16}$, etc., being equal to 1 as it should be." Prof. Karl Pearson repeated Galton's work and practically corroborated his law, although Pearson's fractions differed slightly from Galton's. It is extremely important in considering this law to appreciate that it refers only to the *average* taken from a very large number of cases and that it should not in any case be applied to individuals. The practical application of Galton's two laws of filial regression and ancestral inheritance is obviously of great importance and extremely far reaching. The lack of harmony which exists between these two laws and Mendel's theory of gametic segregation is at once apparent. For an ingenious but reasonable attempt to reconcile the two opposing theories, the reader is referred to Thompson's "Heredity," page 315.

MENDEL'S LAW.

By far the most interesting and important development in the science of heredity is the extraordinary discovery of certain laws of inheritance in plants by Gregor Mendel in the middle of the last century and their rediscovery after years of oblivion in 1900. Mendel's discovery is claimed to have the same relationship to biology as did Dalton's law of constant proportions to chemistry a century age. Punnett, in commenting on the significance of Mendel's discovery, says: "The superstructure of modern chemistry has been raised upon the foundation of the atom; not otherwise may it be with biology, though here, perforce, the analytical process must be lengthier, both from the complex nature of the material and from the greater time involved in

experiments on living forms, for, unlike the chemist, the biologist is trammeled by the times and seasons. Nevertheless, the achievements of the last few years are such as to warrant us in looking forward to the time when our progress in the knowledge of the living may bear comparison not unworthily with the science of the things that are without life."

Gregor Mendel was born in 1822 in Austrian Silesia. He became a priest, and eventually became abbot of the monastery at Brünn. He had received special education in physics and in the natural sciences, in which he was greatly interested. It was his hobby to study the laws of inheritance in hybridizing various plants which grew in the garden of the monastery, and chose for his chief experiments the edible pea, which he found especially suitable for his work, as this plant possesses certain constant differentiating characters and admits of easy artificial fertilization.

Mendel discovered that in crossing two species of the pea which had differentiating characters the offspring resembled only one of the parents. In other words, the differentiating character of one parent appeared to completely dominate the differentiating character of the other parent. When, however, the offspring of the two original parents was inbred, some of the offspring retained the dominating character possessed by the parent, while some exhibited that character of the grandparent which did not appear in the second generation. The amazing discovery was also made that in the offspring of the third generation the number of those which showed the dominant character was always in the proportion of 3 to 1, as compared with the number which showed the suppressed character. Mendel then found that those individuals of the third generation which showed the suppressed character bred true to this character indefinitely. He found too that one third of the members of the third generation which showed the dominating character bred true to the dominant character indefinitely, and that the other two thirds bred in the same way as the members of the second generation.

One of Mendel's classical experiments consisted in crossing a variety of pea which always grew tall with a dwarf variety. The result of this cross was a variety of pea which exactly resembled the tall parent. When, however, this pea was inbred, the result was three tall peas to every one dwarf pea. When the dwarf peas of this generation were inbred, they continued to breed true, generation after generation. When, however, the tall peas of the third generation were inbred, one third of them bred tall peas, generation after generation, while the other two thirds acted in exactly the same manner as the tall peas of the second generation, namely, producing tall and short peas in the proportion of 3 to 1. The quality of tallness in this experiment was called by Mendel the *dominant* character, and the quality of dwarfness was called the *recessive*. This experiment may be best understood by the following diagram, in which *D* stands for the dominant character or tallness and *R* stands for the recessive character, or dwarfness.

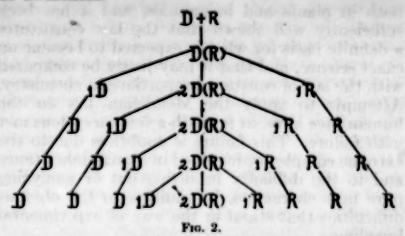

Fig. 2.

The theory which Mendel advanced to explain the results of these experiments was called by him the law of *gametic segregation*. He assumed that when the male *D* and the female *R* gametic cells unite, every cell of the hybrid will contain both *D* and *R*, in which case one dominates, namely, *D*, giving *D* (*R*).

If we assume that in the gametic cells of the hybrid the characters *D* and *R* separate again and go to different cells, half of the gametic cells will contain one character only and the other half the other character. This is supposed to take place both in the male and female individuals. The male gametic cells containing *D* may meet egg cells containing *D* or *R*, and, conversely, the male cells *R* may meet the egg cells *D* or *R*. The possible combinations that may result are shown in the following diagram.

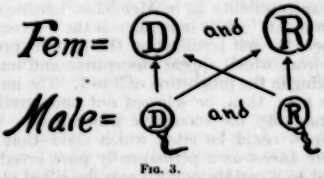

Fig. 3.

There will be two chances of *D* and R uniting to one of *D* and *D*, and one of *R* and *R*. Hence the proportion 1*DD*: 2*D* (*R*): 1*RR*.

Thus it will be seen that Mendel assumed that there were *two kinds of gametic cells* in the hybrid. This theory has stood the test of various experiments, and it is now generally accepted, although it appears to contradict some of the theories of heredity still in vogue. The point of practical importance in Mendel's theory is that perfectly pure bred individuals may be sifted out in future generations from cross-bred ancestors.

The elaborate work of Mendel, of which the experiment here described is only a sample, was published in the proceedings of a local scientific society in 1865. It attracted almost no attention and did not even come to the notice of Darwin, to whom it would have been of incalculable assistance. In the year 1900 the celebrated botanist Hugo DeVries, working independently, and two investigators, Correns and Tschermak, rediscovered the same law, and it was then that Mendel's extraordinary work came to light.

Numerous experiments to test the validity of Mendel's law have since then been carried out, both in plants and in animals, and it has been sufficiently well shown that the law constitutes a definite basis for what is expected to become an exact science, and that it may justly be compared with the law of constant proportions in chemistry. Attempts to apply the Mendelian law to the human race have so far with a few exceptions met with failure. This failure is doubtless due to the extreme complexity involved in human inheritance and to the difficulty in sifting out or analyzing pure unit characters, in addition to the obvious difficulties that stand in the way of experimental breeding.

A few cases where the Mendelian law has been found to work in the human race have been recorded. The two most celebrated examples are one of brachydactylism, and one of night-blindness, The case of night-blindness apparently started as a mutation in a woman who lived in the middle of the seventeenth century. The descendants of this woman, to the number of two thousand, have been carefully traced, and the occurrence of night-blindness has followed closely the Mendelian law.

The following is an example of where the Mendelian law has been put to practical use. Certain forms of wheat are susceptible to the attacks of a fungus which causes the disease called wheat rust, while other forms of wheat are immune. It has been discovered that when the susceptible and the immune forms are crossed, the resulting hybrids are all susceptible to rust, thus susceptibility is, in Mendelian language, the "dominant," while immunity is the "recessive," factor. On self fertilization the hybrids produce seed from which appear susceptible and immune offspring in the proportion of 3 to 1. The immune seeds may, then, be selected out and breed true to immunity for successive generations. Other examples could be cited which show that from impure ancestors a permanently pure breed with regard to a certain quality may be sifted out.

EUGENICS.

The term "eugenics" relates to the improved breeding of the human race. The recent advances which have been made in the knowledge of heredity have awakened interest in the possible artificial improvement of the human race, an idea which dates back to Spartan civilization. Statistics would seem to show that the human race, though rapidly increasing in quantity, is as regards quality tending to breed downwards rather than upwards. It has been shown that there is a greater increase of population among the less desirable element of humanity than among the more elevated strata, and it has also been stated that in all probability the heritable characters of the better element will not eventually be able to dominate the less desirable characters of the lower element. Eugenists foresee an inevitable gradual deterioration of the human race. To prevent this future disaster propositions have been made aiming toward a strict regulation of marriages by law in order to prevent the propagation of unfit individuals. The present complex systems of education and betterment of the human race relate only to the improvement of individuals as they exist, but as the individual transmits only the inborn characters of his germ-plasm, each new individual starts where his parents began and the labors of the preceding generation, though improving his environment, have been of no influence in bettering his natural heritage. As Punnett says: "Education is to man what manure is to the pea. The educated are in themselves the better for it, but their experience will alter not one jot the irrevocable nature of their offspring. Permanent progress is a question of breeding rather than of pedagogics; a matter of gametes, not of training. As our knowledge of heredity clears, and the mists of superstition are dispelled, there grows upon us with an ever-increasing and relentless force the conviction that the creature is not made but born."

Although the average individual in contemplating the progress which the human race appears to be making fails to be greatly impressed with the fears of the more enthusiastic eugenists that the human stock is in a process of mental and physical deterioration, nevertheless it must be granted that there is great reasonableness in many of their views purely from a philanthropic standpoint. It would seem reasonable and feasible even with our present ideas of marriage and human liberty to prevent by law the propagation of criminals, imbeciles, the insane and the actively tubercular and syphilitic. The idea of improving the human race by proper breeding does not in any way conflict with the present ideas of combatting disease and of bettering conditions of the under classes by education and hygienic science. The eugenist believes that such education and careful nurture when applied to the under-average strata of humanity must be coupled with restrictions as to the propagation of their kind in order not to produce eventually an overwhelming amount of deficient stock. It is inevitable that in the course of time eugenistic laws restricting the marriage of the unfit will be enacted, though to what extent it is impossible at present to foresee. A few laws of this nature already exist and prove the feasibility of the movement. When these laws become more general, as in all probability they will within the present generation, the grave responsibility of deciding between the fit and the unfit will rest upon the shoulders of the medical profession, and for that reason it becomes incumbent on the physician to familiarize himself with the important and rapidly progressing science of heredity.

POST-OPERATIVE PSYCHOSES.*

BY JAMES G. MUMFORD, M.D., BOSTON.

SOME years ago I had occasion to look up a large consecutive group of patients operated upon at the Massachusetts General Hospital seven and nine years previously. The purpose of this research was to ascertain what might be their mental

* A paper read before the Philadelphia College of Physicians, Nov. 2, 1910.

condition in relation to the operation, and their present effectiveness as compared with their effectiveness previously. The result of this research impressed me with the fact that we, as surgeons, are regarding too little, perhaps, that condition which Goldthwait has called the ultimate prognosis.

The experienced surgeon of reflective temperament probably considers the psychic elements in his cases, but I doubt if we are aware always how deeply significant those elements may be in controlling the return to health of a surgical patient. Rather are we wont to accept the patient from the hands of his physician; to shrug, perhaps, at what we are pleased to call his neurotic state; to proceed with the operation, if the obvious lesion warrants it; then, with an anatomical cure established, to shift the patient back upon the weary physician for the tedious struggle to health.

I do not maintain that we should refuse to operate upon such discouraging cases. On the contrary, I believe, as Dr. J. W. White long ago taught, that such operations — the operation *per se* — do great good and are important therapeutic measures. My thesis is that we should appreciate clearly the types of individuals liable to suffer from post-operative psychic disturbances, and the surprisingly large number of such persons, and that we should perform the operations of intelligent purpose; and, most of all, that we should recognize our ability to aid in the after-treatment and should bear our share of its responsibility. A competent and experienced dentist has recently stated that he can do little efficient dental work, on his best patients even, within a year after they have experienced any surgical operation. Their psychic equilibrium is so unsettled that they shrink from the slightest manipulation, and must be carried over the year by mild palliative measures.

Let us consider for a moment the significance of certain clinical terms. What is the meaning of the words *cure*, *anatomical cure*, *psychical result*? I take it that a cure is the important end of all therapeutic endeavor. A perfect cure is the *summum bonum*, but is it not true that a large proportion of our cures are relative only? The man with a disabling, recurrent appendicitis is absolutely cured of all pain and digestive disturbance through the removal of his appendix. The man with gangrene of the foot is relatively cured by amputation, though he be left maimed and halting. The woman with an ovarian cyst enjoys an anatomical cure when the tumor has been excised and the wound has healed kindly and soundly, though an unessential organ has been removed.

All these are clinical cures, are cures from the surgeon's point of view; but just here there enters into the problem an element of wide-reaching metaphysical significance. The ills of life, like all the so-called facts of life, are in direct relation and are proportionate to our experiences. The man who has just lost his appendix, if he lacks poise and clear vision, feels that he has been through a grievous crisis, that he has suffered a great calamity in the operation, that the sanctity of his vitals has been violated and that he can never again be what he was. Many persons hold that view, I find. The man who has lost his foot may find little comfort in his freedom from pain and impending death; his old life is gone; he must readjust himself to new circumstances of existence; his relations to his environment must be recast; he must limp, a cripple, through the remainder of his life, bearing with him an unsightly stump and a grievous scar to fret and distress him. The woman whose ovary was removed, useless though that ovary may have been, believes herself to have been unsexed. She has heard tales of changes of temperament, of coarsening features, of mannish tendencies, or perhaps she thinks a full set of ovaries essential to sound health and the bearing of womanly cares. She looks forward to some mysterious, ill-defined change in herself, or to invalidism, and the reassuring farewell words of the surgeon fail to turn her from the expected melancholy course. Strong character and optimism are needed to overcome these tendencies of environment and condition, unless aid be brought from outside sources.

How, then, shall we define a *cure*? I protest that a cure consists only in returning a man to that state of mental and physical health which shall enable him to live his life, to accomplish his wonted work, to adapt himself to his environment in vigor of body and in freedom from pain, with his normal functions undisturbed, with his mind unclouded, buoyant, assertive. That is the perfect cure, but it is a cure not easy of attainment. A more common and reasonable cure is a state of relative comfort and efficiency, with little pain and distress, with infrequent anxiety, with renewed, if imperfect, confidence in the bodily powers.

By the term *anatomical cure* we imply a sound wound healing and a restoration of the bodily functions, so far as such restoration may be compatible with the loss of, or damage to, members and organs.

Psychical results are related to the subjective mind. Their bearing upon the cure concerns the patient, not in proportion to anatomical perfection or potential physical and intellectual capacity, but rather to what he himself feels to be his perfection or capacity; and just in so far as his objective intelligence is feeble, or has become enfeebled, just so far is he fated, on the one hand, to remain a wreck, or, on the other hand, to refit his shattered existence. We must teach ourselves to look to the ultimate prognosis; it is not what we are, it is what we think ourselves to be; that is the sum total of the old argument.

I have spoken of the enfeeblement of the objective intelligence. Such enfeeblement has commonly been referred to as a neurotic condition, and has been regarded often as a state of mind for which the patient is in large measure responsible. In the language of the street, we speak of such persons as lacking in nerve or in pluck, and we are wont to assume towards them an attitude of more or less modified contempt. I believe that

such an attitude on our part is in many instances unjustified, and that through the researches of Crile and his associates we may find excellent anatomical reasons for this depressed mental condition. It would be unprofitable for me here to rehearse the striking and instructive experiments conducted in Crile's laboratories, but one may profitably glance at and sum up some of his conclusions: In a word, he finds that animals and patients, the victims of both mental and physical assaults, suffer quite similar degenerative changes in the structure of the nerve cells in all parts of the brain, and in their reaction to the Nissl stain as well. These changes in the nerve cells include changes in the absolute size of the cells, in the size reaction of the nucleus and plasma, in the membrane surrounding the cell, in the membrane surrounding the nucleus, and finally in the general contour of the cell itself. The cell increases in bulk — from a slight variation to eight times the normal even. In the normal cell there is a definite relation between the size of the nucleus and the remainder of the cell. After operative assault or mental shock the nucleus becomes relatively larger. In the normal cell the surrounding membrane, as well as the membrane surrounding the nucleus, always presents an unbroken continuity. After assault these membranes may be extensively ruptured, so that the cell becomes greatly distorted. In extreme cases the cell loses completely its contour and presents the appearance of a disorganized mass of protoplasm. Furthermore, there are certain notable changes in these cells in their relation to staining. When first assaulted they show an increase in the amount of Nissl stain which they are capable of absorbing; later, as the degree of shock is increased, the amount of reaction to the stain diminishes, so that in the final stages little or no staining is found. Crile observes, however, that in fatal cases, even, all of the cells are not invariably thus altered.

Observe, then, this striking conclusion; on morphological grounds, when shock has broken down the nucleus, the nucleolus and the cell body, so that there remains a mere mass of protoplasm, we must regard the cell as almost certainly dead and incapable of regeneration. The gravity of any physical or mental shock in a given case is indicated, accordingly, by the percentage of brain cells which are thus broken down and virtually killed. The damage done by purely physical trauma is manifest in the destruction of cells in the cortex, in the cerebellum and in the medulla. The cells of the spinal cord are modified little or not at all.

Hertwig, Howard and others, in their studies of unicellular organisms, have shown that in fatigue, overwork and starvation the principal change in the cell is in the nucleus-plasma relation. Crile and his workers have shown that after various physical damage and disease the brain cells obey the same law of change. They find the same changes present as the result of overwork, anemia, infections, drug poisons, shock, fear and anxiety. In acute anemia — and the same is true of fear, fright and worry — we find brain changes varying from temporary hyperchromatism through every stage down to the death of the cell itself. The potential energy of the cell is soon used up. If the effort of the organism does not result in an efficient circulation through the brain and in consequent restimulation of the cell, the patient must suffer collapse, permanent impairment and possibly death. This is a fact of great clinical importance.

Allow me to rehearse an instructive laboratory operation on the intestines by Crile, which resulted in extensive damage to the cells of the cerebral cortex. One can well see that such secondary damage to the cortex might result in prolonged, or even in permanent, impairment of the intellectual and moral vigor of the individual. In a study of intestinal gangrene Crile found that after a certain number of hours of total exclusion of the blood supply the intestine became gangrenous. On his releasing the obstruction the animals soon died, even with the re-establishment of the circulation. If the circulation was not re-established, the animals died also, but later. Even when a preliminary entero-enterostomy had been made, and the isolated coil of intestine was used for the experiment, still death occurred. As a rule there was no peritonitis, and death took place in from twelve to twenty-four hours. If a complete resection of the gangrenous segment was made, death nevertheless occurred in about the same time, but by his making an external drain in the loop of intestine he saved the animal. These results were explained at once by injecting a very small quantity of the juice of the gangrenous coil subcutaneously into a sound animal. Even when the material was injected by a hypodermic needle into the lumen of the uncontaminated bowel, serious illness or death followed, the symptoms being precisely those which resulted from resection for gangrene of the bowel in man. As the experimenter remarks, the coincident widespread impairment of the animal's brain cells told the entire story. Undoubtedly, even at the time of operation in man for gangrene of the bowel, a sufficient amount of toxins has already been absorbed and fixed in the brain cells to cause death; or if there have not been toxins enough, death is made more certain through the amount of poison squeezed into the circulation by manipulation of the gangrenous gut. Patients become severely ill, or die, or remain neurotic invalids, not from the immediate damage to the traumatized part, therefore, but through the more or less permanent damage to the cerebral cortex, as the result of the absorption of toxins. Such an infection as this suggests the rôle which infection plays in ultimate surgical risks. It explains also the slow convalescence in cases of ruptured appendix, with peritonitis, as compared with clean cases. Is it not probable, therefore, that the gross lesions in the abdomen are of less importance to the patient, for life or for perfect recovery, than are the microscopic lesions in the brain?

We have seen, accordingly, and our experience teaches, that many persons subject to physical and mental assaults — to what we call trauma-

tism and to shock — receive serious mental impressions, which can be demonstrated clinically through searching our records, and can be demonstrated anatomically through the examination of the brains of experimental animals and of patients who have died as a result of some form of physical or mental shock. The clinical evidence of disturbed mental equilibrium is familiar to all surgeons, and my researches show me that such mental disturbance is especially liable to ensue after operations on the generative organs of both men and women when those organs have not been actually removed, but have been so tampered with that the patient lives on in dread of their loss at some future time. For example, operations for varicocele and hydrocele are followed by more pronounced and prolonged neuroses than is the operation of orchidectomy. The operations of suspension of the uterus or repair of the perineum frequently leave behind them trains of mental depression more serious than do the operation of ovariotomy, or even of hysterectomy. The explanation in this case seems to be that those deprived of important organs are able to readjust themselves to a positive calamity more readily than are those patients who continue an existence of anxiety regarding a possible future calamity.

A series of investigations by Crile is now in progress on the effects of disturbed functionating of the ductless glands, and so far as this investigation has gone we seem justified in assuming the hypothesis that the ductless glands, — the thyroid, the hypophysis, the suprarenals and the ovaries, — when overstimulated, bring about directly a disturbance or partial destruction of the nerve cells of the brain. We are familiar with the physiological fact that the ductless glands are capable of stimulation through what we call mental impressions, so that, to take a concrete example, we illustrate the circle in some such fashion as this: Excessive fright or anxiety may be the initial cause for a development of the thyroid leading to Graves' disease; Graves' disease results in a more or less continuous intoxication of the whole organism; these toxins bring about a progressive disorganization of certain nerve cells in the brain, and the more advanced becomes this disorganization, the more long-continued or permanent becomes the depressing effect upon what we call the mind as well as upon the functions and the physical capacity of the individual.

In view of this situation, it behooves surgeons to provide in every way possible against adding physical and mental traumata to their patients. This proposition in itself opens a field of wide speculation and interest and of the greatest practical importance. We must endeavor to guard against mental shock by surrounding the patient with appropriate psychic influences, and to guard against physical shock by limiting our operative manipulations to the least possible traumata of the parts involved; and we must employ our anesthetics judiciously and appropriately. Our conduct of convalescence must be made more painstaking, more optimistic and more prolonged. We must impress upon the patient the certainty of his return to perfect health; we must eliminate a needless repetition of painful dressings, which so frequently lead through summation to a depressing dread of the surgeon's visit; and after the wound is healed and the patient leaves his bed we should continue, through ourselves, our associates and the patient's family physician, a constant and sustained attitude of optimism and encouragement to take up and practice the familiar duties and experiences of a well-regulated and normal life.

Clinical Department.

A CASE OF MYXO-FIBROSARCOMA ORIGINATING IN THE GREAT OMENTUM WITH INVOLVEMENT OF THE BLADDER AND SMALL INTESTINE.

BY HUGH CABOT, M.D., BOSTON.

THIS case is reported on account of its rather unusual character and as showing how apparently hopeless growths may at times be found curable by operation.

H. F., Jew, twenty-seven years. Came to the Massachusetts General Hospital Nov. 1, 1909, on account of hematuria. One year ago noticed blood in the urine for a few days. Since that time has had transient attacks of hematuria without pain or bladder irritation. Four months ago first noticed a tumor in the lower abdomen the size of a hen's egg. This has grown rapidly up to the present time. Feels perfectly well and thinks he has lost no weight.

Physical examination. — Thin, poorly developed young man. Examination entirely negative except for abdomen, where there is a tumor rising from the pelvis, filling the space between the umbilicus and pubes and much resembling a uterine fibroid. Its surface was roughly lobulated and it was slightly movable from side to side. Not tender to pressure. Rectal examination negative.

Urinary examination. — Bloody, acid, albumen slight trace. Sediment: Blood and occasional squamous cells.

Cystoscopy. — Bladder holds 9 oz. Mucous membrane is normal except on the roof, where a mass protrudes into the bladder showing a deep cleft in its center, which is red and ulcerated.

Nov. 16. Operation. Six-inch median incision. The tumor proved to be a solid lobulated mass, the size of a child's head, covered by the great omentum, from which it obtained its blood supply. Its lower portion was adherent to the dome of the bladder, while at its upper and right side a portion of the small intestine just above the ileocecal valve was included in the growth. The omentum was tied off in sections along the lower border of the transverse colon and divided, allowing the tumor to be delivered from the abdomen. The small intestine was then clamped, allowing a liberal margin above and below the growth, and divided, leaving a piece of the intestine about eight inches long adherent to the tumor, which was then free except for its attachment to the bladder.

A piece of the dome of the bladder about three inches in diameter was then removed, thus allowing a liberal margin about the growth. The bladder was closed with interrupted catgut sutures through the mucous mem-

brane and muscular coat, and a continuous suture through the peritoneum.

The divided ends of the small intestine were united by end-to-end suture in two layers, the inner with catgut and the outer of Pagenstecher. The gap in the mesentory closed by suture.

A somewhat adherent appendix was then removed and the abdomen closed in layers, leaving a small cigarette drain in pelvis. The bladder was drained with an inlying soft rubber catheter.

There was some reaction on the second day after operation, with moderate distention, some vomiting and a rather rapid pulse. This quickly subsided and he made a rapid recovery. Catheter was removed on the fourth day and bladder gave no trouble.

Feb. 5, 1910. Patient reports to-day having been at work for six weeks. He seems to be entirely well. Urine is normal, scar firm.

Pathological report. — A deeply multilobuated soft, semi-opaque growth 15 cm. in diameter. On one side was a pouch from the bladder 3 cm. deep about which was thickened fibrous tissue. The peritoneum was separated for a considerable distance from the bladder so as to include an area of 5 by 15 cm. in width with the other pouch as a center. Over a considerable portion of the tumor the omentum was thinned out and dipped deeply in between the lobules. On the opposite side from the bladder the tumor was attached to the small intestine by a pedicle 5 by 7.5 cm. along the surface of the intestine. There were several nodules under the peritoneum which had not broken through the mucous membrane. Eleven centimeters of the small intestine had been excised after the growth was removed.

Section of the growth was homogeneous, grayish and semi-translucent.

Microscopic examination showed bundles of elongated spindle-shaped cells alternating with bundles of semi-fibrous character. In places the cells had the shape and appearance of smooth muscular fibers.

Myxo-fibrosarcoma.

Appendix slightly thickened, otherwise not remarkable.

Reports of Societies.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

MEETING OF WEDNESDAY, NOV. 2, 1910.

The President, DR. GEORGE E. DE SCHWEINITZ, in the chair.

CONCERNING NERVOUS DISTURBANCES FOLLOWING SURGICAL OPERATIONS AND ANESTHESIAS.

DR. S. WEIR MITCHELL: In a case of grave hysteria following operation we must consider the patient as a gun already loaded, and that the surgeon merely pulls the trigger. The proper man might know that the gun is loaded. This raises the question whether it is not desirable in many cases to prepare the patient for the operation more often than our surgical brothers seem to think is needed? Not only the risks of death are to be considered, but the possibility of increasing a preceding condition disease. Many physicians have felt that there is necessity for more strictly dealing with the before and after of surgical cases. I shall limit myself to the consideration of the effect on bodily resistance caused by diet and point out the extraordinary effect on the irritability of the bladder produced by a strictly milk diet. So satisfied was Sir James Paget upon this point that he never did a grave operation on the bladder without putting the patient under a fortnight of milk treatment. I am tempted to say that no operation ought to be done without obedience to the rule in St. Bartholomew's Hospital in London, that no surgeon should ever dare to operate on a patient except after consultation with two physicians. Personally, I should not be selfish enough to insist on two, if I were one.

POST-OPERATIVE PSYCHOSES.[1]

DR. JAMES G. MUMFORD, Boston: The frequency of post-operative psychoses is shown by the careful study of cases seven and nine years after operation, taken from consecutive reports in hospital records. The significance of the words *cure*, *anatomical cure* and *psychical results* is discussed. The attempt is made to show that long-continued mental and psychical disturbances following operations are due to demonstrable microscopic changes in certain nerve cells of the brain. The significance of these nerve-cell changes is discussed, together with the method of their production and reasonable measures which may be taken to limit such changes.

THE DIAGNOSIS OF THE POST-OPERATIVE PSYCHOSES.

DR. J. CHALMERS DACOSTA: All sorts of mental disturbance may follow a surgical operation. It is certain that genuine insanity may arise after an operation, though it is seldom met with. Post-operative insanity is more common in women than in men and less common in children than in adults. Contributory causes are pain, insomnia and shock. In all cases of post-operative insanity there is predisposition, hereditary or acquired. A normal, stable brain will probably never go insane after operation unless that operation attack the brain, testicles or ovaries. The anesthetic is usually the exciting cause in insanity coming on immediately after the operation. The commonest type of post-operative insanity is confusional insanity. Fear and worry are two important causal factors. Ante-operation fear may become a post-operative phobia, yet I do not believe that fear or sudden fright is usually responsible for post-operative insanity. Most people go to the operating room with reasonable calmness, many with heroic courage, and some with satisfaction at the prospect. Delirium may be mistaken for insanity, and is far more common, from intoxication or infection, than organic brain disease. The entire subject of post-operative psychoses is one of extreme interest and importance.

POST-OPERATIVE INSANITIES.

DR. EDWARD N. BRUSH, of Towson, Md.: It may be assumed that there is no such thing as post-operative insanity *per se*. Insanity follows operations sometimes, but it manifests itself in various forms. The personal and family history in a given case are so difficult to obtain that we are not at all sure how far mental instability plays a part. This naturally arises from the lack of clinical experience in psychiatry on the part of many observers of these cases. Quite a large proportion of post-operative insanities are due to sepsis, not necessarily from faulty technic on the part of the surgeon. I have knowledge of a woman of unstable mental equilibrium who became insane after the administration of gas for the extraction of teeth and who remained insane for several months. Before we can study intelligently post-operative mental disturbances we must have the histories of our patients carefully recorded. From the lack of this knowledge the post-operative insanity is often erroneously attributed to the operation when in reality the condition may have been present preceding operation.

[1] The paper is printed in full in this issue of the JOURNAL, see p. 838.

DISCUSSION.

Dr. Howard A. Kelly, Baltimore (discussion presented by manuscript in Dr. Kelly's absence): Post-operative psychoses I believe are due to the mental shock of the operation *per se* and not necessarily to any particular kind of operation. The duration and severity of the procedure are minor factors. The condition is due rather to the attitude of intense expectancy, even of dread, inspired by a new and untried force with which the patient feels she has to cope. It is important that the physician should be able to inspire the patient with confidence sufficiently to enable her to feel that he is a moral support. The conditions after operation should be as natural as possible and the patient should be out in the sunlight upon the porch when practicable. Treatment should be prophylactic in determining the predisposing factors. The utmost care should be taken to minimize the unpleasantness of the operation.

Dr. Edward Martin: I think every surgeon in the room feels that when Dr. Mitchell said, "The surgeon pulled the trigger," he practically covered the whole subject.

We do not recognize that a perfectly healthy individual in good mental health can be made insane by any form of surgical intervention practiced at the present day. We do recognize certain post-operative mental disturbances as rather common. We see the type of depression which we call "hospitalism," of which the patient is cured by being sent out of the hospital. We see the type of homesickness, and again the patient is cured by being sent home. We do not see the type mentioned by Dr. Mumford in which the patient is depressed by the thought of loss of organs, and broods upon a physical deformity.

Dr. Francis X. Dercum: The great rôle played by neuropathy in post-operative mental disturbances should discourage operation in such subjects except under circumstances of grave necessity.

Dr. John K. Mitchell: Of 344 cases of general mental or nervous disturbances, there were only 31 cases which could be called post-operative. There seemed to be no relation between the severity of the operation and the severity of the mental disturbance. Fright, I feel sure, plays a larger part than is generally attributed to it. There are good surgical reasons for getting a patient out of bed as soon as possible, but these troubles would be less frequent if the period of rest in bed were increased and general treatment instituted. Should the question of surgical treatment of a neurasthenic patient arise, much more than ordinary care must be observed in deciding upon operation.

Dr. Charles K. Mills: Of many serious cranial operations under my observation I can recall perhaps only two or three in which insanity has followed the procedure. There have been very few also following operations upon the spinal cord. In my experience these insanities have occurred in women of a certain temperament and of a certain predisposition rather than in the neurasthenic type.

Dr. S. Weir Mitchell, closing: The question arises concerning the result of the use of local anesthesia which has become so fashionable in some circles. I hear of abdominal operations done under local anesthesia. I think to have the interior of one's abdomen exposed to one's own view would tend as much as possible to produce some of the insanities of which we have been speaking. It is a fact that occasionally insanities have been cured by grave operations. One such case was an amputation. Another was an attempt on a man's part to cut his throat. The man bled almost to the point of death, but his life was saved, and he recovered from his insanity. I don't recommend the method. The greatest of surgeons known to me is the surgeon called "War," and I have seen many cases in which sudden delirium or sudden delusion followed instantly upon a gunshot wound. One case was that of a colonel who, after being shot, cried to his men to run, that the rebels were upon them. He fell to his face, was delirious for some time, but, after amputation of his arm, he returned to the regiment that evening. Another case was that of an officer in the Mexican War, a man of well-known courage. A ball struck his heel; he limped up and down the line calling to his men to run, that everybody was going to die, and for hours he was in a condition of the wildest maniacal excitement. This passed away within forty-eight hours. He asked for a court of inquiry, which, of course, was denied a man so well known for courage.

Book Reviews.

Founders' Week Memorial Volume. Edited by Frederick P. Henry, A.M., M.D. Published by the city of Philadelphia in commemoration of the two hundred and twenty-fifth anniversary of its founding. Philadelphia: 1909.

This volume contains an account of the celebration of the two hundred and twenty-fifth anniversary of the founding of the city of Philadelphia, and "histories of its principal scientific institutions, medical colleges and hospitals." It is a compliment to the editor, not lack of appreciation of his labors, to say that the most interesting part of his work is his epigrammatic preface. The book is a useful compilation of valuable historic data about the many charitable, scientific and medical institutions and enterprises which have justly made Philadelphia famous in the past, and still distinguish her in the present. The illustrations, though not beautiful, are well adapted to their purpose of supplying information. The volume should be a serviceable work of reference for those interested in the history of the city and her activities.

Practical Points in Nursing. For Nurses in Private Practice. With an Appendix containing Rules for Feeding the Sick; Receipts for Invalid Foods and Beverages; Weights and Measures; Dose List; and a Full Glossary of Medical Terms and Nursing Treatment. By Emily A. M. Stoney. Fourth edition, thoroughly revised. Containing 97 text illustrations and 8 colored and half-tone plates. Philadelphia and London: W. B. Saunders Company. 1910.

This new edition of Miss Stoney's well-known book on nursing presents a large amount of fresh material incorporated with the excellent substance of the original. The illustrations are numerous and in the main good. The volume should continue to be a popular and valuable textbook for training-schools and for nurses in private work.

Diseases of the Colon and Their Surgical Treatment. (Founded on the Jacksonian Essay for 1909.) By P. Lockhart Mummery, F.R.C.S. Eng., B.A., M.B., B.C. Cantab.; Jacksonian Prizeman and late Hunterian Professor, Royal

College of Surgeons; Senior Assistant Surgeon, St. Mark's Hospital for Cancer, Fistula and Other Diseases of the Rectum, etc. Illustrated by colored and other plates and numerous figures in the text, many of which are reproduced from the author's sketches. New York: William Wood & Co. 1910.

This little book of three hundred and seventeen closely printed pages is founded upon the author's Jacksonian prize essay, awarded by the Royal College of Surgeons in 1909. It is a most useful and informing handbook. The subject of diseases of the colon is not altogether so recently developed as he implies in his preface. Nevertheless, much bad work is still being done in colon surgery, and much misinformation still is current regarding this organ. Mummery takes up his subject systematically, and deals with the colon's anatomy, functions and diseases in proper sequence, winding up with excellent chapters on colon operations. He is not in accord with those writers who regard the colon as of small importance to the organism. He reminds us that the absorption of water takes place mainly in the colon, so that elimination of the colon is wont to result in chronic diarrhea and a chronic thirst. He points out also the danger of leaving blind pouches when operating on the colon, since these pouches, through retro-peristalsis, become filled with hardened fecal masses which act as a source of auto-intoxication and mechanical injury.

Among a multitude of interesting paragraphs we read of the best methods of examining the colon; of post-operative complications; of such lesions as kinking, relieved by properly applied massage; of ptosis and its treatment; much of mucous colitis, for which the author advocates appendicostomy; of antero-spasm; of diverticulitis, which is forcing itself more and more on our attention; much of chronic constipation, in regard to which he discusses Arbuthnot Lane's method of ablation of the colon, and with a note of distrust; and at length, of the great subject of tumors of the colon. The book is admirably written, is extremely suggestive and is well worth study alike by physicians and by surgeons.

Physiology and Pathology of the Semicircular Canals. Being an Excerpt of the Clinical Studies of Dr. Robert Barany, with Notes and Addenda gathered from the Vienna Clinica. By ADOLPH E. IBERSHOFF, M.D., and a Foreword by ROBERT S. COPELAND, M.D. Pp. 64. New York: Paul B. Hoeber.

This is a small book of 64 pages. The title and the following extract from the foreword accurately set forth the nature and the purpose of the book: "Since the publication by Ewald and Hoegyes of their epoch-making experiments on the semicircular canals of animals, and the discovery of the underlying laws of labyrinthine physiology, extensive researches have been conducted at the clinics of Vienna and Berlin on the human labyrinth. While the latter have been supplemental to the classical work of the above-named pioneers, they have served to reduce the subject to a practical basis and to evolve a new and valuable method of diagnosis of conditions hitherto obscure. Nystagmus, which until recent years has been associated almost entirely with congenital or early acquired optical defects, or in an indefinate way with lesions of the inner ear, has become one of the most important aids in differential diagnosis, and greatly amplified the scope and efficiency of the aurist.

"With the exception of a few contributions to our medical journals by men who have recently visited the Vienna clinica, this is the first attempt to present the subject in detail to the English-speaking profession."

After discussing the anatomy and the physiology of the semicircular canals, the writer takes up nystagmus and describes the methods of determining it in the normal and in the pathological labyrinth. The tests by which nystagmus can be elicited, namely, the caloric tests and the turning tests, are clearly given and their physiology clearly explained. The subject of labyrinthine vertigo is also given concisely and clearly.

The differential diagnosis of the labyrinthine conditions and the operative measures indicated are given. The book ends with a set of tables condensed from Mackenzie. These give in parallel columns the differential points necessary in distinguishing labyrinthine suppuration, peri-labyrinthitis, neuritis of the eight nerve and cerebellar abscess.

This book is a timely and valuable one. As the writer says, it is one of the first, if not the first, to give this puzzling subject in English. The usefulness of the book would be increased and the subject made more complete if the writer had added a discussion of nystagmus and vertigo in diseases of the cerebellum.

Dawn of the Fourth Era in Surgery, and Other Short Articles. By ROBERT T. MORRIS, M.D., Professor of Surgery, New York Post-Graduate Medical School and Hospital. 12mo. Pp. 145. Philadelphia and London: W. B. Saunders Company. 1910.

Morris's writing is always stimulating and suggestive. He has sometimes been criticised for undue vigor of statement, for exaggerating minor matters and for loudly crying down methods and teachings which do not meet with his hasty and somewhat boisterous sympathies. These criticisms may possibly express the views of impatient conventionalists only. At any rate, the little book before us is full of good reading. The author has collected in a convenient pocket-volume his most important journal essays of the past five years: that paper which he calls the Physiologic Era in Surgery, his description of various diagnostic points on the abdominal wall, the papers on the appendix, on surgical cleanliness, et cetera. The essays are written in a popular and picturesque style, and for the larger medical public. Doubtless they may at times lead astray the unwary and inexperienced, but who admits himself to be inexperienced or unwary?

THE BOSTON
Medical and Surgical Journal.

THURSDAY, DECEMBER 1, 1910

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 Tremont Street, Boston, Mass.

OUR HETEROGENEOUS URBANIZED POPULATION.

The work of the census is nearing completion, and though it is still too soon to draw definite conclusions, certain inferences from it seem fairly warrantable. The total population of the United States, including the Philippine Islands and Porto Rico, is approximately 104 millions; that of the United States alone is about 93 million, as against 76 million ten years ago, representing an increase of about 22%. This sounds gratifying; but when it is remembered that this increase is largely by annexation and immigration, that our native birth-rate is rapidly declining, and our shores filled with swarming alien hordes not fundamentally in sympathy with our racial institutions and ideals, the prospect seems less pleasing. Our country is to-day in the situation of a highly gorged anaconda, replete with heterogeneous material. Can this indiscriminate mass be assimilated? Can our racial genius so leaven the nations as to fashion them all to our form and substance? These are the questions which we face with our unabsorbed and seemingly unabsorbable millions. Nothing but the spirit which can solve these "in the teeth of all the schools, will save us at the last."

Another very striking aspect of our growth in the past ten years is the increase of large cities. We now have 50 cities with a population of 100,000 or more, and nearly a third of our people live in cities of over 25,000. New York City alone contains more people than the rest of New York state. This urbanization of population is not peculiar to the United States. It is characteristic of all modern civilizations. With it goes all that city life implies of bad hygienic environment, nervous wear and tear, and moral degradation. With it also go all the advantages and opportunities for progress and splendid achievement which are possible only in corporate urban society. The conclusion is one neither of elation nor of pessimism. The result of the census shows that we are following natural paths of evolution. If we would have a high civilization, we must be prepared to pay for it, and it can be purchased only at the cost of an urbanized population which makes its necessary activities possible. Man's instinct for aggregation is perhaps representative of the primitive impulse that brought the myriad component cells of his being into symbiosis. Moreover, there are positive elements of encouragement. If our population is urbanized, it is also suburbanized. Our cities have spread their limits proportionately more than they have swelled their numbers, with the result that many now who are officially city-dwellers have many of the blessings of country life. This combination of the two is, perhaps, the keynote of our solution. So far as hygienic environment goes, too, our cities are fully as healthful as many country districts, as is proved by their water supplies, their watchful prophylaxis of disease, their low death-rates. The alertness of the medical profession is one of our greatest guarantees of safety under conditions that might otherwise become hazardous. Altogether, then, the prospect is one of encouragement, and in meeting it, it behooves us to remember that our profession has a greater opportunity for service in America, with her urbanized people and her unassimilated millions, than in any other country in the world.

THE PROPHYLAXIS OF CROUPOUS PNEUMONIA.

The pneumonia season is at hand. This disease keeps on claiming an enormous and increasing number of victims. It constitutes about 2% of all internal diseases and is responsible for nearly 10% of all deaths in the United States to-day. The mortality for tens of thousands of cases remains where it was one hundred years ago — between 20 and 25%. The day is probably coming when we shall have a specific for pneumonia, but until that day comes we must fight the disease as we have in the past, and we can hardly expect a decrease in mortality.

In one respect, however, we can improve on the past, and that is in the matter of prophylaxis. Although we cannot cure more cases than formerly, we can many times prevent the occurrence of the disease. In many cases of pneumococcus pneumonia there is a history of recent infection,

generally severe, somewhere in the respiratory tract — a bad "cold in the head" or a follicular tonsillitis, laryngitis or bronchitis. The patient recovers, perhaps without being obliged to give up any of his ordinary duties, and seems perfectly well to himself, his family and his physician. But he may be harboring the pneumococcus all the time, and after his resistance has been lowered by business worry or long hours of work during the holiday season, by the frightful dust of the snowless streets and finally, perhaps, by careless or unavoidable exposure on a cold or wet night, the deadly micro-organism has his chance. We ought to take more seriously the cases of acute respiratory infection which come under our observation, especially between November and June, when most cases of pneumonia occur. A case of acute bronchitis should not be allowed to pass without a sputum examination. If pneumococci are present, the patient should be kept in bed as long as there is the slightest fever, and after that he should be treated as a convalescent from pneumonia. He has had a pneumococcus infection, and, after all, pneumonia itself is only a pneumococcus infection with local manifestations in the lung.

A still better way to prevent pneumonia is to avoid the previous infection of the upper air passages. People who live in city streets should cleanse the nose, mouth and throat every night as a routine measure. The pneumococcus, according to Musser and Norris, has been isolated from the throats of 50 out of 80 normal individuals. Wells demonstrated it in the respiratory passages of 62 out of 135 persons examined. Convalescents from pneumonia may carry virulent organisms in their throats for weeks or even months. The chief source of the pneumococcus is the sputum of the pneumonia patient. Woods found that the organism could live in moist sputum as long as two weeks. When the sputum becomes dry, pneumococci can be easily distributed on dust particles in the air. The patient, in coughing, sneezing or talking, expels into the air "droplets" which may contain pneumococci. The Medical Commission for the Investigation of Acute Respiratory Diseases in New York finds that infection may be acquired by the inhalation of dried sputum or of freshly exhaled droplets suspended in the air of the sick room, or by contact with utensils used by pneumonia patients. According to Woods, the danger from infected sputum can be avoided by ample illumination (sunlight) and ventilation of the sick room and by refraining from dry sweeping and dusting. Sputum cups should be insisted upon. The best way of disinfecting the sputum is by keeping a strong solution of sodium hydrate in the cup. Corrosive sublimate and carbolic acid do not disinfect the central portion. The patient should be isolated from all except those taking care of him, and articles which may be contaminated and which cannot be cleaned by cloths dampened with a disinfectant should be removed from the patient's vicinity. Isolation in hospital wards is desirable. A physician should never pass from a pneumonia patient to a patient with some other disease without washing his hands.

HOSPITAL BUREAU OF STANDARDS AND SUPPLIES.

THE recently published first annual report of the Executive Committee of the Hospital Bureau of Standards and Supplies presents a statement of the work of the Bureau during the first seven months of its existence, ending Sept. 30, 1910. This new and interesting organization was established last spring in New York for the purpose of securing to hospitals "the advantages of co-operation in establishing uniform standards as to quality and kind of supplies ordinarily used therein and of purchasing the same in accordance with definite specifications under continuing or other general agreements, and for the purpose of promoting the economic and efficient administration of such hospitals."

Five New York hospitals entered this co-operative association, to which nine others have since been admitted. The Bureau has already formed 21 agreements, of which 17 are still in force, covering such articles of supply as ice, coal, gauze, incandescent lamps, bottles, pins, meat, adhesive plaster, toilet paper, paint, blankets, coffee, towels and alcohol, and already has shown a substantial saving in the purchase of such articles above the cost of administering the Bureau.

The project certainly seems one of great value and efficiency. Its continued success depends on the number of institutions which become affiliated with it, since each new member reduces the expense of maintenance for the rest. It is purposed to establish a non-resident membership for institutions outside New York City. The Bureau affords admirable illustration of the benefits of intelligent co-operation, and the widening of its usefulness should result in the establishment of similar associations among hospitals in other sections of the country.

IMMUNITY OF ANIMALS TO POISONS.

The varying susceptibility of different animals to the several vegetable and mineral poisons is well known. Dogs tolerate large quantities of morphia, and elephants eat codeia with apparent impunity. A large trick elephant, executed in New York last week for having killed her keeper, lived forty-four minutes after swallowing 500 gr. of potassium cyanide. Nor is this tolerance solely a matter of proportionate bulk, because the hedgehog is also highly resistant to cyanic poisons. Moreover, this fortunate animal has a high degree of immunity to the toxins of diphtheria and tetanus, and to snake venom. There is opportunity for considerable investigation and perhaps valuable discovery in the comparative study of animal sera and immunity.

MEDICAL NOTES.

Pellagra in South Carolina. — Report from Spartanburg, S. C., states that of 332 deaths in that city thus far this year, 21 have been due to pellagra.

Epidemic Conjunctivitis in Virginia Military Institute. — It is reported from Lexington, Va., that the Virginia Military Institute in that city has been closed until Jan. 4, 1911, on account of epidemic conjunctivitis among its pupils. The nature of the infecting agent is not stated.

Bubonic Plague in Manchuria. — Report from St. Petersburg states that bubonic plague is now epidemic throughout Manchuria. Rigid precautions are being observed along the frontier to prevent entrance of the infection into Siberia.

Illness of Queen Elizabeth of Belgium. — It is reported from Brussels that the illness of Elizabeth, Queen of the Belgians, which was at first supposed to be bronchitis, has now been diagnosticated as typhoid fever. Her majesty is said to be progressing favorably.

Smallpox in Michigan. — Report from Lapeer, Mich., states that about Nov. 6 smallpox became epidemic among the inmates of the State Home for Feeble Minded in that city, since which time there have been 30 cases and 14 deaths of the disease. The institution is under quarantine, enforced by a military guard.

Cholera in Italy and Canada. — During the week ending Nov. 26, 29 new cases and only 4 deaths of Asiatic cholera were reported in Italy, where the epidemic seems to be distinctly subsiding. The Russian suspect, detained at Quebec, Canada, to whom we refered in last week's issue of the Journal, is said to have proved a genuine case of cholera, but is recovering.

Death of a Cretin in Oregon. — From Canyonville, Ore., is reported the death, on Nov. 21, of a girl thirteen years old and weighing only fourteen pounds, presumably a cretin, who had not enjoyed the therapeutic advantages of thyroid extract.

Death from Headache Powders. — The recently reported simultaneous sudden death in Brooklyn, N. Y., on Nov. 25, of two women with signs of acute poisoning, after taking headache powders procured of two different druggists, re-emphasizes the dangers of such remedies obtained without prescription. An investigation is being made of the contents and place of manufacture of the powders.

Cinematographs of Tuberculosis. — The National Association for the Study and Prevention of Tuberculosis has made arrangement for the simultaneous exhibition this week, in a number of moving picture theaters throughout the country, of a series of films illustrating the modes in which tuberculosis is transmitted and the methods by which it may be combatted.

Some Charitable Bequests. — The will of the late Mrs. R. G. Dun, who died recently at Hot Springs, W. Va., was filed for probate on Nov. 22 at Narragansett Pier, R. I. Among several public charitable bequests it contained one of $20,000 to the Orphan Asylum of New York City, and one of $5,000 to the Home for Blind Babies at Bay Ridge, N. J.

Gift of Land for a Tuberculosis Sanatorium. — It was announced last week at Colorado Springs, Colo., that James K. Polk Taylor of that city has given a tract of 480 acres of land at Calhan, Colo., to the Charles Sumner Tuberculosis Association as a site for a National Tuberculosis Sanatorium for negroes, which is to be erected at a contemplated cost of three hundred thousand dollars. Mr. Taylor was born a slave, but since his emancipation has become a prosperous landowner in the West.

Appeal for North Shore Babies' Hospital. — An appeal to the public is made by the officers of the North Shore Babies' Hospital for money which is urgently needed for immediate repairs and improvements in the diet kitchen, laundry

and bathroom. This free institution does a valuable charitable work, and its needs should not be unheeded by those who are able to give.

RELATIONS OF ANIMALS TO HUMAN TUBERCULOSIS. — In an address last week before the Boston Scientific Society, Dr. Edwin H. Schorer described the varieties of tuberculosis in animals, other than man, and particularly those animals, like cattle, dogs, cats and parrots, with which man comes into more or less close personal contact. He emphasized the importance of this relation in that it affords opportunity for transmission of latent forms of the disease, if not of direct infection.

LECTURES BEFORE THE NURSES' CLUB. — At the regular fortnightly meeting of the Nurses' Club of Boston, this evening, Dec. 1, Dr. Cleaveland Floyd will deliver an address on "Newer Methods of Treating Pulmonary Diseases." At the meeting on Dec. 15, Dr. Charles R. C. Borden will speak on "Diseases of the Ear, Nose and Throat, and their Influence on the General Health." The public is cordially invited to these lectures, which will be given at 8 P.M. in the rooms of the club at 755 Boylston Street.

CONTINUANCE OF THE TYPHOID EPIDEMIC AT ANNAPOLIS. — During the week ending Nov. 26, three more new cases of typhoid fever were reported at the United States Naval Academy at Annapolis, making a total of twenty students now ill with the disease. There have been no deaths, and all the patients are said to be progressing well. It is believed that the source of the infection has been traced to a temporary extra supply of milk which was used at the Academy from Oct. 19 to Nov. 9. The occurrence of this epidemic should give weight to the Surgeon-General's recent recommendation that anti-typhoid inoculation be made compulsory in the army.

CUT RATES IN PROPRIETARY MEDICINES. — A suit is now pending before the United States Supreme Court involving the legality of "cut rates" for proprietary medicines. The suit was originally brought before the United States Circuit Court by a company at Elkhart, Ind., which undertook to restrain the sale of its medicines at reduced prices by a firm in Cincinnati, Ohio. The desired injunction was refused, and this decision was sustained by the Circuit Court of Appeals. The suit, which has now been appealed to the Supreme Court, is based on a series of contracts by which the manufacturers attempt to control the prices of their goods. The decision of this question will have an important bearing on the problem of "cut rates" in all proprietary medicines.

INHIBITION OF A PSEUDO-MEDICAL COLLEGE. — Under the law forbidding the use of the word "college" by an unchartered institution of learning, the New York State Education Department issued on Nov. 25 an injunction against the so-called "American College of Science" in Rochester, N. Y., an establishment which has been conferring unauthorized degrees in mesmerism, hypnotism and personal magnetism. This action was taken on complaint by the consul-general from Guatemala that several graduates of this institution were practising in his country. In not desiring their presence, the inhabitants of Guatemala seem to have been more sensible than some of our own citizens. It is to be hoped that the injunction may serve to check at least one of the forms of dangerous pseudo-medical charlatanism which are rampant in the land.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, Nov. 16, 1910, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 41, scarlatina 28, typhoid fever 9, measles 20, smallpox 0, tuberculosis 67.

The death-rate of the reported deaths for the week ending Nov. 16, 1910, was 16.56.

BOSTON MORTALITY STATISTICS. — The total number of deaths reported to the Board of Health for the week ending Saturday, noon, Nov. 19, 1910, was 211, against 174 the corresponding week of last year, showing an increase of 37 deaths, and making the death-rate for the week, 16.33. Of this number 107 were males and 104 were females; 204 were white and 7 colored; 118 were born in the United States, 92 in foreign countries and 1 unknown; 48 were of American parentage, 139 of foreign parentage and 24 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 42 cases and 0 deaths; scarlatina, 19 cases and 0 deaths; typhoid fever, 9 cases and 4 deaths; measles, 22 cases and 0 deaths; tuberculosis, 50 cases and 18 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 33, whooping cough 0, heart disease 32, bronchitis 5. There were 14 deaths from violent causes. The number of children who died under one year was 36; the number under five years, 49. The number of persons who died over sixty

years of age was 71. The deaths in public institutions were 81. Anterior poliomyelitis, 2 cases.

Of the above infectious diseases the following were non-residents: Diphtheria, 1 case. Consumption, 1 death. Scarlet fever, 1 case. Anterior poliomyelitis, 1 case.

Deducting deaths of non-residents, the total is 183 and the death-rate is then 14.16.

Arrests for Promiscuous Spitting. — Prosecution of the so-called "spit war" is still proceeding vigorously in Boston. During the week ending Nov. 26, 63 arrests for illegal expectoration were made in the city, and nearly all the prisoners were fined two dollars each. Ten of them, being unable to pay the fine or furnish bail, were obliged to spend one or more days in jail.

Deportation of a Case of Trachoma. — In September last, an Armenian immigrant, who had entered this country from Halifax, N. S., in July, was arrested at Boston, found to have trachoma, and ordered deported. In the interim, she had married an American citizen, and now on this basis claims immunity from deportation. Whatever the technical merits of her case, it is to be hoped that she will not be allowed to become a menace to others by remaining at large with an infection of such serious nature.

Punishment for Illegal Sale of Cocaine. — The prisoners, whose recent arrest in Roxbury for illegal sale of cocaine we chronicled in the issue of the Journal for Nov. 17, were tried last week in the local district and were each sentenced to imprisonment for terms varying from one month to four months. Several of them appealed and were held in bonds of three hundred or four hundred dollars. It is to be hoped that their punishment may be not greater than they can bear, but severe enough to act as a deterrent to them and to others in the future.

Two Centenarians. — Mrs. Delima Beaudry, who died last week at Woonsocket, R. I., is said to have been born on Nov. 25, 1809, at St. Anne de la Parade, P. Q., Canada, the eldest of a large family of children. She was twice married, and by her first husband had sixteen children, of whom six, together with all her own younger sisters and brothers, survive her.

Mr. Hubbard Blakeslee of Ridgefield, Conn., locally reputed to be one hundred and three years old, was burned to death on Nov. 24 in a barn at Southport, Conn., where he was staying in charge of a prize stallion and a drove of hogs. The accidental upsetting of an oil stove is supposed to have been the cause of the disaster. It seems hard that a man of his advanced years should meet death by violent rather than natural means.

An Ancient Peacock. — Man is not the only animal that sometimes lives to great age. The longevity of elephants and parrots is proverbial. Report from Sulphur Well, Metcalfe County, Ky., states that one of the farmers of that district possesses a peacock known to have been alive in 1800 and still in vigorous health.

A Lamentable Instance of Dishonesty. — Dishonesty among members of the medical profession is always exceptionally lamentable, dishonorable and unpardonable, for they have greater occasion than any other class of men to learn the value and sanctity and prevailing greatness of truth, and are doubly bound to practise the principles which they recognize. It is with the greatest regret that we learn that three graduates of the class of 1897 in dentistry in Harvard University, an institution dedicated to Truth, have been blacklisted by the Harvard Athletic Association for selling to speculators football tickets which they had themselves purchased under an express stipulation not so to dispose of them. There can be no question as to their deliberate dishonesty. They should have been beyond such mercenary temptation. Their conduct is a disgrace to their profession. They deserve the ignominy which attaches to their punishment.

NEW YORK.

Department of Bacteriology at Museum of Natural History. — A department of bacteriology has recently been inaugurated at the American Museum of Natural History on Manhattan Square.

Lecture on Public Health. — On Nov. 21 the lecture in the public course at Columbia University on "Public Health Protection" was by Dr. Simon Flexner, of the Rockefeller Institute. His subject was "The Rise of Bacteriology," and in concluding his discourse he remarked: "In no other natural science has practical achievenent followed more quickly and surely upon what in the beginning was thought to be abstract knowledge."

Safety Devices. — A permanent exhibition of safety devices, under the auspices of the American Museum of Safety, was formally opened on Nov. 21 in the Engineering Societies Building on

Thirty-ninth Street, near Fifth Avenue, and on this occasion an illustrated lecture was given by Dr. W. H. Tolman, the director of the museum, who has recently returned from a study of similar institutions in Europe. It is the hope of the founders eventually to make it equal to the great museum of safety in Berlin. It will be the aim not only to encourage the development of safety devices, but also to develop sanitary appliances tending to reduce the death-rate among workmen in the various trades.

SALE OF PROPERTY OF SOCIETY FOR RELIEF OF RUPTURED AND CRIPPLED. — The New York Society for the Relief of the Ruptured and Crippled has sold its hospital property on Lexington Avenue, extending from Forty-second to Forty-third Street, for $1,350,000 to the New York Central Railroad Company, which by this purchase acquires the final piece of property required to complete its plans for the enlargement of the Grand Central Station and yards. By the terms of the sale the hospital will not vacate its buildings for a year, by which time it is expected that a new hospital, in a less central location, will be ready for occupancy. It is also purposed to have a country annex for convalescent patients. The Society for the Relief of the Ruptured and Crippled was founded in 1863, largely through the instrumentality of the late Dr. James Knight, who remained at the head of its hospital until his death. In 1867 it purchased the large property just sold and erected the building at the Forty-second Street corner, and the adjoining building fronting on Forty-third Street was constructed fifteen years ago.

PAGE LAW AND PHYSICAL EXAMINATION OF WOMEN. — That part of the Page law for the inferior criminal courts, passed by the last legislature, which provides for the physical examination of women, has been declared unconstitutional by Justice Bischoff, of the New York Supreme Court, in an opinion handed down on Nov. 25 in *habeas corpus* proceedings brought to release a woman confined in the workhouse. The writ was granted on the ground that the statute directs the detention of the accused without due process of law, in that the sentence is made to depend upon the report of a physical examination without the opportunity for a hearing upon the facts entering into the report. The statute, which went into effect on Sept. 1, provides that women, on conviction, may be held for any time short of a year within the discretion of the magistrate.

DEATH OF "QUEEN." — It took forty-four minutes to kill a female elephant with 600 gr. of potassium cyanide, at the winter quarters of a circus in Jersey City, on Nov. 25. It was determined to execute "Queen," as she was called, for the vicious killing of one of her keepers, and the poison was administered in six capsules, which were put into three pails of "bran mash." The elephant, which weighed 7,650 lb., was one of the largest ever exhibited in America, and was believed to be nearly ninety years old.

5. MITCHELL, J. R. *A New Theory of Eclampsia.*

2. Stanton and Krida write a valuable paper on the subject of electric shock, reviewing the literature and reporting their experiments on dogs. They find that the two great causes of death are cardiac fibrillation and respiratory paralysis. Low-tension currents usually kill by producing fibrillary contractions of the heart, in which the individual muscle fibers contract in an utterly incoördinate manner. As the tension is increased, the effect on the heart becomes less pronounced and the effect on the central nervous system more and more certain, so that with high-tension currents death is more likely to be caused by respiratory failure. Cardiac fibrillation is always fatal. In cases of simple respiratory paralysis, the patient may be kept alive by artificial respiration until the nervous system recovers from the effects of the shock. [L. D. C.]

6. Pilcher, from the examination of the gastric contents in four thousand cases, believes that there is a definite entity presented in the stomachs of patients suffering from various intra-abdominal and extra-abdominal pathologic conditions which is characterized by the absence of hydrochloric acid and the presence of "occult" blood. This condition is probably produced by a nervous reflex inhibiting first the production of free hydrochloric acid to only a moderate degree, but enough to allow the increased growth of pathologic bacteria, such as the streptococcus and colon group. These act as direct irritants in conjunction with such primary irritative factors as gallstones, appendicitis, pancreatitis, and produce an ulcerative erosion of the mucous membrane which gives the "occult" blood found in these cases. These are, therefore, not cases of "achylia gastrica," as shown by the prompt return to normal when operative relief from the primary extragastric condition is effected. Such cases occur in about one in every fifteen stomach cases.

8. Litchy also bears out Pilcher's observations in a series of experimental observations on dogs, in which perigastric lesions were produced in the gall bladder and appendix, or pouch of the cecum, and were followed or accompanied by a hypo-secretion of hydrochloric acid and the presence of "occult" blood. Litchy also found a decrease of acidity during starvation and an increase following excitement.

9. Skoog advises lumbar puncture, both for diagnosis and relief of symptoms in the early stages of acute poliomyelitis, especially when there is any tendency to meningeal embarrassment. He also uses hexamethylenamin, 0.12 to 0.24 gm. doses, during this stage, and in other non-infected children in the same family, as a prophylactic. He believes that rest is of greatest importance and if rigidly enforced may abort some cases of paralysis. He also quarantines all cases and urges that it should be made a reportable disease throughout the United States.

11. Camac, C. N. B., and Milne, L. S. *The Spinal Cord Lesions in Two Cases of Pernicious Anemia.*

1. McCrae discusses the subject of diffuse dilatation of the aorta as illustrated by a series of sixty cases. Two main groups of cases occur, the first following acute infectious diseases, notably rheumatic fever, and the second having its etiology in the causes of arteriosclerosis and aneurysm, although syphilis probably plays a less prominent rôle than in true aneurysm. Clinically the condition may exist without symptoms, or with symptoms which may be explained by coexistent myocardial or valvular disease, but many cases complain of dyspnea and thoracic pain of varying degree. Pressure symptoms and signs are common, but rarely severe. The chief physical signs are visible pulsation in the upper interspaces, dullness over the upper sternum and changes observed by means of the x-ray. The importance of recognition of this condition as distinguished from aneurysm lies in the much more favorable prognosis of the diffuse dilatation.

3. Eshner reviews the various methods that have been used to induce thrombosis in aneurysmal cavities with special reference to wiring and electrolysis. He reports 2 cases and has collected 38 from literature. He concludes that while aneurysm of the aorta is essentially a fatal disorder, in sacculated forms wiring and electrolysis is a simple and safe procedure and has led to satisfactory results in a majority of instances where its use has been reported.

6. Edwards reports a case of febrile pylephlebitis which promptly recovered when given antisyphilitic treatment. From a study of literature he finds a number of descriptions of syphilitic conditions simulating septic disorders of the liver.

9. Rachford has treated two cases of status lymphaticus by means of x-rays with distinct improvement. The thymus gland, which was distinctly large to percussion, became smaller and the thymic asthma disappeared.

7. White, W. C., and Van Norman, K. H. *An Individual Quantitative Index to Tuberculin Dosage in Treatment.*

1. Hamman reports a study of the heart-muscle in forty-three fatal cases of typhoid fever. He compares this with the clinical histories of the same patients, and finds that, although there were changes in the heart-muscle in every case, there was no direct relation between the severity of the pathological changes and the clinical manifestations of the disease. Irregularity of rhythm and the physical signs of beginning dilatation occurring during the course of an infectious disease are, Hamman thinks, fairly certain signs of some cardiac lesion. In the cases which he studied, he frequently met with peri-arteritis and endarteritis in the large and medium-sized branches of the coronary arteries, and from this he concluded that the acute infections may have a late deleterious effect upon the circulatory system, even if they do not affect it during the acute attack.

3. From their study of ergot, Wood and Hofer conclude that ergot is a stimulant to all the unstriped muscle tissue of the body, hence it has a stimulant effect on the arterial muscles and probably on the heart. The active principle they believe to be an alkaloid — hydro-ergotinin — which, in combination with a resinous body, forms sphacelotoxin. The percentage of sphacelotoxin varies accurately with the physiological activity of different specimens of ergot.

Fluid extract of ergot deteriorates so rapidly that even under the most favorable conditions there is a loss of strength approximating 10% a month, and if the drug is exposed to the air, the loss is even greater.

5. Fleisher and Loeb, by injecting spartein or caffeine and adrenalin into rabbits, produced a condition of overwork for the heart-muscle which resulted first in edema of the muscle, later in small areas of fibrosis. The site of this lesion at the base of the ventricle they think points to a purely mechanical explanation for the change, instead of pointing to the theory that the lesion is due to lack of nutrition of the muscle fibers involved. In order to apply this theory to man, it would be interesting to know whether the immediate effect of the injection upon the general circulation of the rabbit is more or less severe than the effect of athletic feats or "strength stunts" upon the circulation of man. [G. G. S.]

1. Pool and McClure have in the last year performed twelve transfusions by the end-to-end suture method of Carrel on ten patients. Many records of the hemoglobin, red and white cell counts, pulse-rate and blood pressure were made. The cases were secondary anemias of various causes, except one of gas poisoning and one of septic endocarditis and septicemia. Both these cases died; the first from extensive destruction of brain cells, the latter from her weak heart, which was unable to tolerate the increased burden of the transfused blood. Four cases (probable hemophilia, a severe anemia with high color index in which three transfusions were done, papilloma of the bladder, and infected uterine fibroid with pyemia) were apparently raised from the grave.

3. Carrel reports the successful resection of the abdominal aorta repaired by a graft consisting of a somewhat larger section of the vena cava in three animals. All were allowed to walk and eat as usual after a few hours. The deaths were completely independent of the operations (one killed by chloroform ten months after operation owing to the development of a pyelonephritis; another died apparently of old age three months after operation, and the third lived in perfect health for fourteen months, then died in a few days of pneumonia). The condition of the aorta and venous segment were studied. The anastomoses were excellent. The venous wall reacted against the arterial blood pressure by thickening its wall (an increase in connective tissue, probable increase in muscular fibers, and occasional increase in elastic fibers, but not observed in these experiments).

4. Blair and McGuigan have, on dogs and cats, experimentally produced air embolism and tried various measures for resuscitation. Some animals succumbed after the injection of very small quantities of air. Other animals recovered without treatment after the injection of much larger quantities of air. There was always a fall of blood pressure, dyspnea and restlessness. Respiration always stopped before the heart, owing to the ineffectiveness of the heart-beat in pumping blood to the respiratory center. Cardiac massage alone failed to remove air from the heart. The injection of fluid to fill partially the right heart and sweep the air into the pulmonary circulation failed because the weakened heart could not tolerate the burden of volumes of fluid sufficient to accomplish this result. Fluid plus an instantaneous powerful cardiac stimulant was tried. The authors suggest for the human 2 ccm. of 1:1,000 adrenalin solution injected directly into the right ventricle accompanied by saline solution. They do not state the amount of saline, but used in their animals 40 to 100 ccm. The strain of the injection may be lessened by simultaneous bleeding from a peripheral vessel. The Schafer method of artificial respiration is recommended when respiration ceases.

8. Von Eberts describes an airtight dressing and drainage device for use after rib resection in the treatment of empyema to favor the expansion of the lung and to demonstrate the daily amount of discharge.

9. Maylard and Anderson present two unusual cases of primary gastric sarcoma, one a unilocular cystic tumor with long pedicle, without stomach symptoms, and mistaken for an ovarian cyst.

11. Bartlett describes a continuous, single-row suture embracing all coats suitable for the anastomosis of all hollow viscera. It has been used exclusively by the author for two years with perfect satisfaction.

12. Davis has investigated the rectosigmoidal anastomosis in twenty-one subjects, in some by dissection of the vessels, in others by x-ray pictures of the vessels injected with a starch-lead-oxide mass. The female showed no variations peculiar to her sex. The anastomotic loop between the sigmoid and superior hemorrhoidal was found on an average 1.5 cm. below the promontory of the sacrum (in one case it was 5 cm. below). In several cases bifurcation of the superior hemorrhoidal occurred before the sigmoidal loop joined the rectal supply, in which cases ligation immediately above the loop (Hartman) would be dangerous. In the majority of cases Davis confirmed the wisdom of clamping vessels as far from the rectum as possible when operating by the sacral route, for the loop usually lay close to the bowel, but in some cases the loop arises so far from the bowel that the observance of such a rule would be disastrous. Two cases showed no loop.

13. Scudder completes the record of a case previously reported.[1] An amputation at the shoulder-joint had been done for sarcoma of the humerus. Microscopic examination of the removed tumor showed it to be hypernephroma. While still under the anesthetic a slight enlargement of the left kidney was made out. This was symptomless. Nephrectomy was urged on the ground that no other metastases could be found but was refused. Almost five years later death occurred, and a complete autopsy showed no local return and no other metastases. This case may be added to the series of Albrecht (Hochenegg's clinic) of hypernephroma with solitary bone metastasis. [T. W. H.]

2. Loeffler recommends a new method for detecting small numbers of tubercle bacilli. It is a modification of the antiformin method, and consists in dissolving with antiformin and then centrifugalizing after the addition of a mixture of alcohol and chloroform. He gives the technic in detail.

4. Munk, as a result of some experimental work on rabbits, has come to the conclusion that the new Ehrlich preparation does not affect the Wassermann reaction. Whatever it is that the spirochete produce in the serum to give the positive reaction seems to be produced also by the spirochete after destruction by the new preparation.

6. This author found that the blood serum of animals attacked with foot and mouth disease showed on the addition of an extract of the virus a specific diminution of surface tension, so that there were more drops in a given volume. This test seems to last for some time after the attack. [C. F., Jr.]

11. Fessler, J. *A Non-Irritating Method of Drainage for Wounds.*

2. Beneke advances the view that in infants with open fontanelles tension on the dura is of great importance in both acute and chronic cerebral diseases. A sudden lateral compression at birth may rupture the tentorium and may result in sudden death, protracted asphyxia or other mild or severe symptoms. Chronic increase of tension may be brought about by habitually laying the infant on its side. This increase of tension is due to compression of the longitudinal sinus by the weight of the head, and it may lead to chronic internal hydrocephalus or to hypertrophy of the brain.

5. The writer, working in Sumatra, obtained positive Wassermann reactions in large percentages of frambesia and leprosy, and in a considerable number of cases of malaria. One group of malarial cases having strong positive reactions before treatment continued to show them after the fever was gone. These were regarded as probably syphilitic. In other cases an incomplete reaction was present before treatment was begun, but disappeared entirely in a few days. [G. C. S.]

11. Bauer, A. *X-Ray Illumination without the Screen.*

6. The author has found that the earliest evidence of experimental tuberculosis in the guinea pig is in a pair of glands which lie behind the jugular vein. These glands he has found consistently enlarged and the seat of tubercular lesions from the eighth to the fourteenth day after an injection of tubercular material, while evidence of disease in other parts of the body does not manifest itself until after the lapse of from three to five weeks. The author describes his technic and the article includes an illustration. [J. L. H.]

6. Schueffner, W. *Pseudotyphus of Deli.*
7. Stoerk, O. *Electrocardiograms.*

3. Working with dogs, Mayerle finds that with repeated similar doses of thyroid extract hyperthyroidism comes on gradually and shows itself by (1) a negative nitrogen balance, i. e., a storing of nitrogen; (2) an increased output of water; and (3) increased burning of fats.

Loss of weight occurs if (*a*) there is not reserve absorption enough to compensate for loss; (*b*) the demand of the body is supplied by an easily assimilable substance, such as pure albumin.

4. The authors describe atony of the esophagus as a condition of the esophagus in which soft food is hindered in its passage, while fluids and large masses are passed along in a normal manner.

They classify thirteen cases under this head, excluding from the classification such conditions as paralysis of the esophagus, esophagismus and cardiospasm. The diagnosis depends upon x-ray findings, backed up by negative results with the esophageal sound. Normally soft solid food is waved down the esophagus in a few seconds by regularly following peristaltic waves, showing by fluoroscope as approximately four distinct masses; in conditions of atony the food lies, a thin pillar, the whole length of the esophagus, peristalsis being insufficient to break it up. That the condition is not one of spasm is shown by giving water, whereat the whole mass quickly glides into the stomach.

Most patients showing atony are neurotic, as a rule exhibiting signs and symptoms of an hysterical character. Atony may also be a temporary disturbance in organic nervous disease, may be the result of local pressure, as, for example, by the heart, or may be a manifestation of general weakness, and it is naturally one component of a sluggish gastro-enteric tract.

Symptomatically dysphagia may be complained of, but more frequently the condition is not brought to light without questioning. Its diagnosis, as said, depends upon x-ray examination with bismuth, the technic of which is given.

5. The authors report three cases of coronary thrombosis with autopsy, and two cases without, and review several others. Symptoms were found to be of three types: (1) Pain was present in all of the cases, in two exhibiting radiation into neck, head and left arm; attacks were of five- or ten-minute intervals, with remissions at first, later becoming continuous to death: a status anginosus. (2) Dyspnea in two was very marked, accompanied by Cheyne-Stokes respiration, so-called status dyspnoeicus. (3) A sense of pressure in the epigastrium, status gastralgicus. All forms may be accompanied by nausea and vomiting. Signs: Cold and cyanotic skin; weak but usually regular heart action, though rapid; first sound often doubled, but no murmurs. There is evidence of peripheral anemia, venesection in one case causing no flow, and accompanying internal congestion, as shown by an enlarged liver.

History of previous anginal attacks was the rule. As for the duration of terminal attacks, three lasted a week, two less than forty-eight hours.

The essential difference between the diagnosis of coronary thrombosis and angina pectoris lies in the prolonged character of the pain in the former, be it status anginosus, status asthmaticus or status gastralgicus. [J. B. A.]

26. SUDECK, P. *Observations on High Extirpation of the Rectum.*

1. From an extensive series of experimental inoculations in animals, and from a bacteriologic study of 49 cases of various forms of human surgical tuberculosis, Burckhardt reaches the conclusion that the tuberculosis of cattle plays only a very subordinate part in the production of tuberculosis in man and that the most available means for combatting tuberculosis should be directed primarily to the prevention of infection from human sources.

4. On the basis of a case of his own observation, and of similar cases which he cites from the literature, Gangitano describes as a clinical entity a cordition of diffuse chronic peritonitis following trauma and associated with serious vascular lesions, especially of the venous system under the form of phlebosclerosis. The course is slow and progresses with ascites, so that it is not always differentiable from traumatic cirrhosis of the liver. With the extension of the peritoneal lesions, other abdominal organs may be involved. Associated with the phlebosclerosis may be a desquamation of the vascular endothelium, which the author regards as representing in all probability an irritative mechanical lesion following the peculiar conditions of the vessel walls produced by the disease process.

7. Dilg reports a case of congenital infantile pyloric stenosis successfully treated by operation, but in his discussion of the literature makes no reference to the work done on this subject by Scudder, Murphy and other American surgeons.

11. Tavel reports six cases of non-malignant goiter successfully treated by endothyreopexy, a procedure first described by Gangolphe. As a result of his experience, the author advocates the operation in complete bilateral degeneration of the thyroid, in recurrent struma after unilateral extirpation when there is paralysis of the inferior laryngeal or when the remaining part of the gland is degenerated, and in bilateral compression of the trachea when after extirpation of one side further prolongation of the operation is inadvisable. The technic consists of (1) provisional or permanent ligation of the superior thyroid and possibly central ligation of the inferior; (2) mobilization of the gland; (3) enucleation or partial resection thereof; (4) isolation and suture of the stump in a pocket between the sterno-cleido-mastoid and the skin, with stitches through the fascia and the tendinous portion of the muscle; and (5) drainage and suture of the skin.

15. The authors, presenting the results of their research in experimental vascular surgery, recommend the use of a simple continuous silk suture, including all the coats of the vessel, in the repair of traumatic vascular defects. By this means they obtained 40% of successes in arterial suture and 60% in venous. Small arteries and large veins gave better results than large arteries and small veins. In losses of vascular substance up to 2 cm. in extent, they advise mobilization and approximation of the ends and union by circular suture; but if the loss exceeds this amount, they prefer vessel transplantation. Six months after the termination of their experiments they had observed no formation of aneurysm at the site of a suture. [R. M. G.]

BULLETTINO DELLE SCIENZE MEDICHE.

5. From a microscopic study of the testicles of adult rabbits before and at varying intervals after section of the

nerves supplying them, Ugolini finds a decrease of the spermatogenic and an increase of the interstitial cells of the gland following such section. In the event of unilateral section there is compensatory hypertrophy of the remaining side. [R. M. G.]

Miscellany.

LIGHT LABOR FOR CONSUMPTIVES.

In one of our daily papers there recently appeared the following item relative to the value of light labor in the treatment of pulmonary tuberculosis:

"An interesting matter wherein English institutions differ quite a little from those in this country is the arrangement of some kind of light labor for tubercular patients. The Frimley Sanitarium of Middlesex is an example of this method. The patient on arrival is given the easiest kind of work, such as the carrying of a light basket of stones a certain distance each day, preceded perhaps by some regulated amount of walk. If this work produces a rise of temperature and reaction, the patient is put to bed with absolute rest. It is found that the anti-tuberculin generated by this rise of temperature has usually made the patient more resistant, so he is able then to do the work that caused the temperature. On resuming work the amount of his labor is gradually increased until before the patients leave the hospital it is no unusual thing for them to be able to labor six hours a day with pick and shovel. The patients have done extensive landscape gardening about the grounds and have built an excellent concrete reservoir. They take care of the animals about the place and do a great deal of the work about the house. It is believed that the morale of such patients is higher than that of those taking the cure of absolute rest."

A few days later there appeared as a reply in the same paper, a letter by Dr. Arthur T. Cabot, chairman of the trustees of the Massachusetts Hospitals for Consumptives, the concluding paragraphs of which seem also to deserve republication:

"It will doubtless be of interest to your readers to know that the trustees of the Massachusetts Hospitals for Consumptives, who have under their charge the four sanatoria, containing eight hundred beds, in this state, have from the outset fully recognized the important part that work plays in promoting the cure of consumption. Following in the footsteps of Dr. Paterson, who did pioneer work in systematizing the introduction of this treatment and in pointing out the scientific basis on which it rests, they have encouraged their superintendents to introduce it in the institutions under their charge.

"The superintendents met with some difficulty at first owing to the mistaken idea among the patients that rest is the important factor in treatment for those who were comparatively well, just as it admittedly is for those who are very sick and feverish.

"This error is rapidly disappearing under patient explanation, and the convalescents now have occupations adapted to their strength, which promote their cure and put them in fit physical condition to take up their ordinary habits of life when they leave the sanatorium.

"It is greatly to be hoped that the local boards of health and anti-tuberculosis societies will keep a watch over the arrested cases that go out of these institutions; will see that they get work suited to their condition and that they continue the open-air life which is of such importance in preventing a relapse.

"Whether this work is done thoroughly or not depends largely on the people. They must see that the anti-tuberculosis associations and committees have enough funds to enable them to employ nurses to keep up a supervision of these cases, and they must make sure that active men enlightened in matters of hygiene are selected for the boards of health."

For an interesting and somewhat detailed account of the system in vogue at Frimley we refer readers to our Paris Letter of Feb. 10, 1908.

AMERICAN SOCIETY OF MEDICAL SOCIOLOGY.

The American Society of Medical Sociology has recently been formed in New York by a number of physicians "for the purpose of investigating the social causes of disease and other problems of a medico-social nature." Dr. Abraham Jacobi has been elected honorary president of the society, Dr. William J. Robinson its president, and Dr. James P. Warbasse vice-president.

Among the topics already suggested for study by this society are occupation and trade diseases, the relation between the stress of modern life and the increase of insanity, food adulterations and their influence on health, tuberculosis as an economic disease, the probable causes of cancer, the alcohol problem, the causes and prevention of infant mortality, the causes and control of quackery, marriage and divorce, eugenics, race suicide and venereal disease. Many of these, it will be observed, are already under investigation by more limited special societies.

Correspondence.

THE ADVISABILITY OF THE ESTABLISHMENT OF A STATE HOSPITAL FOR CASES OF NERVOUS BREAKDOWN.

Boston, Nov. 27, 1910.

Mr. Editor: In the issue of the Journal of Nov. 24, there appears a short article entitled "Desirability of a State Psychopathic Hospital," in which the writer seems to have confused the suggested state hospital for cases of nervous breakdown, in regard to the advisability of which the hearing was held, with the Boston Psychopathic Hospital which the state has already voted to establish in connection with the Boston State Hospital. The suggested hospital for cases of nervous breakdown, while it might admit cases of border-line psychoses, would include more especially those cases of nervous exhaustion which have been known to the profession under the names of neurasthenia and psychasthenia, and would not intentionally contain any insane.

I enclose a copy of the resolve under which the commission was created.

Very truly yours,

William N. Bullard, M.D.,
Secretary of the Commission

LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND OTHER OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDED NOV. 16, 1910.

GASSAWAY, J. M., surgeon. Leave granted Oct. 14, 1910, amended to read twenty-four days from Oct. 7, 1910.

WHITE, J. H., surgeon. Granted ten days' leave of absence from Nov. 11, 1910.

NYDEGGER, J. A., surgeon. Granted one month's leave of absence from Nov. 10, 1910, on account of sickness.

SPRAGUE, E. K., surgeon. Leave of absence granted Oct. 14, 1910, amended to read four days from Oct. 28, 1910.

GRUBBS, S. B., passed assistant surgeon. Granted twenty-one days' leave of absence from Nov. 7, 1910, on account of sickness.

FOSTER, M. H., passed assistant surgeon. Granted seven days' leave of absence from Oct. 3, 1910, under paragraph 191, Service Regulations.

KORN, W. A., passed assistant surgeon. Directed to proceed to Pittsburg, Pa., upon special temporary duty. Nov. 7, 1910.

EARLE, B. H., passed assistant surgeon. Granted three days' leave of absence en route to station.

ROBERTS, NORMAN, passed assistant surgeon. Granted two days' leave of absence from Nov. 7, 1910, under paragraph 191, Service Regulations.

SMITH, F. C., passed assistant surgeon. Granted seven days' leave of absence from Nov. 3, 1910, under paragraph 191, Service Regulations.

SPRATT, R. D., passed assistant surgeon. Granted seven days' leave of absence from Oct. 14, 1910, under paragraph 191, Service Regulations.

COFFEE, JOSEPH H., acting assistant surgeon. Granted ten days' leave of absence from Nov. 5, 1910.

HAMILTON, H. J., acting assistant surgeon. Granted four days' leave of absence from Nov. 4, 1910.

SCHUSTER, B. L., acting assistant surgeon. Granted twenty-two days' leave of absence from Nov. 7, 1910.

STUART, A. F., acting assistant surgeon. Leave of absence granted for thirty days from Oct. 1, 1910, amended to read thirty days from Oct. 4, 1910.

WALKER, T. D., acting assistant surgeon. Granted eleven days' leave of absence with pay and one day's absence without pay from Nov. 7, 1910.

WALKLEY, W. S., acting assistant surgeon. Granted two days' leave of absence from Nov. 4, 1910.

WETMORE, W. O., acting assistant surgeon. Granted two days' leave of absence, Oct. 10 and Oct. 30, 1910, under paragraph 210, Service Regulations.

WHITE, R. C., acting assistant surgeon. Granted thirty days' leave of absence from Nov. 7, 1910.

SCOTT, E. B., pharmacist. Granted four days' leave of absence, without pay, from Nov. 9, 1910.

TROXLER, R. F., pharmacist. Granted one day's leave of absence, Oct. 30, 1910, under paragraph 210, Service Regulations.

HOLT, E. M., pharmacist. Granted two days' leave of absence from Nov. 7, 1910, under paragraph 210, Service Regulations.

STIER, CARL, pharmacist. Granted one day's leave of absence, Oct. 31, 1910, under paragraph 210, Service Regulations.

RECENT DEATHS.

DR. FREDERICK LARKIN, a retired physician of Randolph, Cattaraugus County, N. Y., died on Nov. 24, at the age of ninety-seven years.

DR. JOSEPHUS REGUS, who died last week at Rochester, N. Y., was born in 1832. He was a dentist by profession, but was also well known as a student and inventor of rapid-fire ordnance.

DR. ALVAH C. VAN SYCKLE, of Hackettstown, N. J., died suddenly from cardiac disease, on Nov. 22, while attending a meeting of the Warren County Medical Society. He was a prominent citizen of Hackettstown and had served as mayor of the city.

DR. DUDLEY PAGE COTTON, who died at Roxbury last week, was born in the Barbadoes, West Indies, in 1849. He was educated at St. Paul's School, Concord, N. H., and at Trinity College, Hartford, Conn., from which he received the degree of A.M. in 1871. Subsequently he studied medicine at the University of Edinburgh, Scotland, and served for a time at the Royal Maternity Hospital in that city. On account of ill health he never undertook the general practise of his profession, but became a student and traveler. He lived for many years in London, and also at Dresden, Germany. He is survived by two sisters and four brothers. He was unmarried.

DR. STEPHEN GUERNSEY COOK, of New York, died on Nov. 21, in the eightieth year of his age. He was born in Dutchess County, New York, and was graduated from the medical department of the University of the City of New York in 1857. During the Civil War he served as surgeon in a Dutchess County regiment, and at the close of the war located in New York. He was appointed a police surgeon in 1873, and for many years was president of the police surgeons' board. He was one of the founders and incorporators of the Medical Association of the Greater City of New York, and at the time of his death was president of the West Side Savings Bank.

DR. WILLIAM ROBERT BROSS, of New York, medical director of the Equitable Life Assurance Society, died from cerebral apoplexy, on Nov. 21, at his residence at Babylon, Long Island. He was a native of New York City and fifty-six years of age, and was graduated from the College of Physicians and Surgeons in 1881. Going to Central America, he served for several years as port health officer at Port Limon, Costa Rica, and later as consulting commissioner on yellow fever in South America. Dr. Bross joined the staff of the Equitable Life as assistant to Dr. Edward Lambert, the medical director, in 1889, and at the latter's death was appointed senior medical director.

"WHAT MEDICAL SOCIETIES CAN DO FOR THE HEALTH OF THE PEOPLE." *

BY JOHN RITCHIE, JR., BOSTON.

THE question has been asked of me, "What can a Medical Society do for the health of the people?" This question I am going to try to answer in part this evening, and from the point of view of the layman. And worse than this even, like the reviewer of a book who lets no peep into its pages prejudice his mind with facts, I have not sought to know the precise purposes of the Suffolk District Medical Society, and have asked for no glance at its constitution or by-laws, but have constructed my own society, and this from the layman's point of view as to what such a society should be.

While I was a member of the Board of Health there were times when it seemed to me as if the influence and authority that such a society ought to wield might have been an important factor towards the rational consideration of important questions.

For a point of beginning, let me present to you the status of the health of Boston, for that is the locality in which we all are interested and in which the work of a local society would begin. The lantern slides will present a general view of health conditions past and present and will afford an opportunity to note in a way where advances are needed and where they may be made.

Let me say here at the outset that Boston has no occasion to be cast down in the least about its health conditions. There has been some wild statement now and then that it is not in line with other great cities in the country and that radical changes ought to be made in the methods, and it has even been suggested that if this city is to be abreast of its sister cities in the country it will be necessary to import some sanitary leader to show Boston physicians what to do. Of course there may not be foundation to such statements, but they have been current in the newspapers, and it has even been stated that a former mayor was in Washington on precisely such an errand.

It would need much more than an evening to follow out the figures that establish the condition of the health of Boston in its comparison with those of other cities. This is not a sum in simple subtraction; it is quite a complicated problem, and the editor who wrote for a Boston paper, "The health of Boston is mediocre; not so good as that of Chicago or New York," would have difficulty in getting a true statistical basis for so sweeping a statement. A society of this kind should, it seems to me, have a true knowledge of the health figures of its home city.

With reference to the imported sanitary leader, I shall have more to say anon, but it seems to me that here is precisely the kind of question that an authoritative local society could consider intelligently and with which it ought to be thoroughly competent to deal, if it is willing to devote sufficient time to it, in the interests of the public good.

But to come to the sanitary story of Boston. Here are a few diagrams presenting some of the larger conditions, prepared by me for my own personal study.

[There followed then a series of five lantern projections presenting graphic diagrams of the vital statistics of Boston. These were the general and steady decline in the mortality-rate from all causes, the great decline in the death-rate for the common infectious diseases, the decrease in deaths from tuberculosis and the status of infantile mortality, i. e., of children of less than one year of age.]

Here, then, are the health conditions of Boston; what can a society like this do to improve the record? It is evident that it must come among the refinements of mortality work, for the coarser problems have all been considered, and with a success that you may judge of by the diagrams. Now what is there in the way of betterments to a pretty good condition that a society like this can help effect?

And I would like to interpolate here that this condition of health rates is due to the good judgment of the helmsman who has guided for more than a third of a century the actions of the Board, and it is creditable that in that time no serious mistake has been made. There has been lots of adverse criticism on the part of the press and individuals, and what has been done has not always had the full approval, in fact, has evoked the opposition of some medical men, but when from a secure future one has looked back on the course of the Boston Board of Health, it will be evident that almost every important sanitary advance for the country has had its initial point in Boston. I can say this without self-praise, for my brief relationship with the Board was too short for me to leave an impress on its actions or to be entitled to much of any credit for its good works.

It is perfectly true that Boston seems at times to be behind some other cities, but there are two things here to be remembered: that a good health officer must be conservative and not be carried away by the fads of the moment, and, again, that Boston is spending but thirty-three cents per capita per annum for its health, while other cities have found the means to expend much more.

There is the story in which you gentlemen, as physicians, ought to have interest and pride, for it is upon you, in the final analysis, that the responsibility must rest. It is true that there is a Board of Health, and it may seem to be wielding despotic power and be arbitrary, but it can act only with the support of the intelligent men of its community; its work on the whole cannot be maintained above the standard of the medical men and the citizens who support it. The function of a Board of Health, in a number of aspects, is admirably stated in the June Bulletin of the Massachusetts State Board, which says, "The medical profession must remember that the Board of Health acts only as the agent of the

* Read at the meeting of the Suffolk District Medical Society, Oct. 29, 1910.

profession in assembling the data provided by them, and depends upon them for their willing co-operation."

Now, gentlemen, there is the nub of the whole matter, and in ratio to the faithfulness with which you perform your part, the success of the whole will be assured. And here my own personal opinion comes in, that while the counsel and aid of individual physicians is always given to the officials, still it seems to me that it ought to be a function of just such societies as this to give the same kind of support better and more forcefully and with a stronger impression on the public.

In my humble opinion a great and representative society like this ought to be a support to those who are in the leading health places. It ought to know what is being done; it ought to be in touch with the work; it ought to know something of the financial requirements. It ought to be ready and willing to give its advice when advice is needed, and also its firm support. It ought to be able to give an opinion from which all petty and personal conditions have been eliminated, and it ought not to be slow in coming forward with that opinion when the opinion is timely.

A group of public officers finds itself subject to all kinds of attacks and from many quarters; a group of health officers in particular is subject to such attacks. In Boston there have been times when the Board of Health has had its work and its methods called into question by those who had no knowledge or appreciation of the true facts, but who are persistent in their warfare. Where the work has been as faithful and as creditable as it has been here, criticism of the kind is wicked, for constant dropping will wear the stone. Inertness on the part of medical men, inactivity of societies that might have given authoritative support to the right, are responsible in part for this.

Now let us get to direct consideration of some of the matters that have thus far been merely suggested. There is the membership of the Board of Health. It is most important, and yet, so far as concerted action by medical men is concerned, it has been practically neglected. Occasionally some progressive physician individually recommends or supports his man. It is true that, as a principle, medical bodies have no place in politics, but the Board of Health of a municipality ought to be far above politics. It has responsibilities that transcend the usual considerations and demand the services of the best men. This fact will be appreciated by the people just in ratio to the extent that medical men themselves appreciate it. If they are themselves watchful of the best health interests of the community, they will have the right to be watchful over the personnel of the group of men who have the health of the community in their keeping.

I believe that it is possible for a society like this, the segregation of the best thought in the medical work of a great city, so to speak that it will make itself heard; and, being heard, impossible to be ignored. A society like this, it seems to me, ought to abandon the principle, not to speak till spoken to and not to give advice till asked, but should be ready to present its opinions well digested and matured at the proper time.

There has been a great deal of talk backwards and forwards about importing a sanitarian for the chairman of the Board of Health, of a single head, of reorganizing, and divers other radical changes. These are all of them, it seems to me, matters in which a society like this ought to be a leader and a maker of opinion. It ought to formulate its own opinion first, and this ought to be expressed.

The proposition to import a chairman, it seems to me, is an important one for just such a society to discuss. Here was a slap in the face to the whole medical profession of Boston, an assertion that, notwithstanding its Institute of Technology, its medical schools and its thousands of skilled physicians and sanitarians, there was no one among them all competent to be chief medical and sanitary executive. Other places are pulling away from Boston men to put at the head of important sanitary work, and Boston has lost such leaders as Hill, Rickards and Slack, and no one has said "Boo." Then, when seemingly through the authority of an executive it was said, "We propose to seek elsewhere for a sanitarian, for Boston has none competent," the whole medical fraternity pocketed the affront. To me as a layman the situation was extraordinary and I watched the columns of the medical journals for some sort of reply.

There are a good many questions pertaining to public health that come to be subjects for legislative consideration. I think that here a society like this could work much benefit by telling the truth. Last year there was a discussion about meat from tuberculous cows. There was a good deal of misinformation abroad; it was a question where the definitions were antiquated, where new ones are necessary and where distinctions are not well understood by the laity, who freely discuss and act on such things, and there were opportunities for misinterpretations. A few men stood forth for the right as they understood it before legislative committees, but they were individuals and voiced only their own personal opinions. A society like this, it seems to me, could have clarified the matter and, with a reputation behind it, could have formulated an opinion that no legislature could misunderstand.

I do not know that the Suffolk District Medical Society is yet in a position to do this, because it may not have yet acquired that reputation in its own country as a prophet and adviser that would make its opinion acceptable. But I know that it has all the factors to such a reputation. Is it not your duty to your home city, that, being such a society, with such possibilities, you exercise what are your rights? Other societies do such things, and some of them are now quoted far and wide. You can, if you wish, become the authority for a country by no means limited by your own Suffolk district.

A little while ago it was the question of the quality of the milk supply of the city of Boston. You know, and I know, that, by the standard of

cities of its class, it is good. I know that it is probably as good as that of any large city in the country and difficult to improve save at greatly increased cost.

Now in this movement a leader has arisen who is anxious to put into force a system of inspection of the farms, "so that," he is quoted in the newspapers as holding, "the germs of infectious disease may be kept out of the supply." Supposing that a great society could say officially that until a physician can be maintained at every milk-producing farm, there is a possibility that infection may creep in at any time, the situation would certainly be clearer. No matter what it said, if it had the authority behind it and the confidence of the community, it would have influence for the right.

Suppose a society with reputation and authority had said, "The ultimate test of the quality of a milk supply is the infantile mortality; Boston heads the list of cities in this country in this respect," would it not have been a statement not to be disputed? But if I say it, and I have said it with all the force that I, personally, have been able to carry, I am but a man, conceited in his own ideas.

Just now it is the question of pasteurization of milk. There is here a problem in sanitation for which at the moment I see but one solution. I believe a proper pasteurization to be the only present means out of the difficulty of milk infection. It is going to meet with opposition; it is probable that medical men are not to-day nearly a unit in opinion, but it is a question of the very close future. This society ought to be formulating its opinion. It can have the advice of milk experts, it can get anything in the way of precise information that it wishes, and with these in hand it can have an opinion. This will not be the diversity that individuals cannot avoid, but one with the authority of a strong medical body behind it. In New York the experiment in milk has been made. It is said that Strauss was driven from his position by the opposition of a newspaper. If his position is truly a right one, and there had been a calm and authoritative medical society to back him, public opinion would also have been to the support of Strauss, and the backward step need not have been taken.

Thus far the considerations have been in the group that might be termed larger public questions, in which a medical society might stand as an adviser to the executive and law-making authorities of commonwealth and municipality, and incidentally aid in the education of the people. Let us now turn to a consideration of some of the matters wherein an association like this may help in the educating of its own members, by the presentation to them and to other members of the profession of certain plain duties towards the improvement of the public health.

I wish now to speak on a matter pretty directly connected with the diagrams — that of reporting. As is evident from the diminution of infectious diseases, the coarser methods of work have been pretty well tried out, and the advance of the future must be along lines of refinement. The reporting of cases is the most important present need in the warfare against infectious disease. It is the most essential feature in the fight at the bedside, which is the proper place for the battle as waged in these times. Philosophically considered, infectious diseases would absolutely cease could all the cases be isolated, and while this is impossible in practise, it is the desire of health officers to approach as nearly to this condition as may be possible. Here the authorities are absolutely at the mercy of the physician, for while there are laws compelling notification, it seems rather hard to make criminals of reputable physicians for what they, themselves, regard a peccadillo. And again, it is not so easy to press to conviction in a matter where the evidence is so technical and in which only the grossest violation could not be defended through lack of exact diagnosis or some such subterfuge. Notification seems to be, so far as many physicians are concerned, a matter in which personal opinion is entitled to much weight. I have had a good medical man whisper in my ear about the nonsensical notion of making further demands on the time of the physician by increasing the number of notifiable diseases. As the result of many factors, notification, while it is improving year by year, is not so well or so fully carried forward as it should be. The improvement must be by the education of the physician. There are many factors towards neglect; for example, the patient is a tuberculate, the family feels, as families usually feel, that it is a kind of disgrace, the individual shrinks from publicity and the physician fails to notify.

Here is a work in which a society like this can help enormously by creating an *esprit du corps*. The society as a society does not question the fact that notification is wise; it knows that no disease is added to the list without a great deal of consideration and discussion by the authorities. Individuals hastily question all these things, and, acting on their own impulses, anxious, perhaps, to please their clients, neglect notification. A society can help materially in improving the health conditions by making it popular to notify.

Anterior poliomyelitis is a notifiable disease and has been so for about eighteen months. It seems to be very imperfectly reported in Boston to the local Board of Health. Boston, in the second half of 1909, had 35 cases reported. The State Board of Health reports in the whole of 1909, in Boston, 299 cases. There is a discrepancy here. I have not thought it worth while to spend time locating this obvious neglect to notify. It is new to physicians, they are not used to reporting it, the state has wished especial information and has issued special circulars, and in notifying the state it is probable that physicians have thought themselves to be doing their whole duty. But in this there is needed a little bit of education. The fundamental notification is by law to be given to the local board, and the Boston Board of Health ought to bear on its books through notification from physicians all the cases within its limits. What the state or the individual chooses to carry

on as a special investigation should not interfere with the legal notification.

Especial attention has this very week been directed by the typhoid committee of the Massachusetts Association of Boards of Health to the need of strict practise of notification. It is too often the case that the disease is taken as a matter of course, and little attention paid to it. The plea of the committee is broader than merely notification, and goes directly to urge treatment of typhoid fever as an infectious disease, and to have it recognized by physicians and boards of health for what it really is, — a great menace to the public health.

Incidental to notification, there is the care with which it is done, and thoughtful physicians may aid the authorities materially. The cards used in this city request certain facts about the disease and the patient and also the name of the milk dealer. There is nothing asked that is not of immediate importance, no fact that the physician may not easily get. Yet many cards are received deficient in some of the particulars. You can readily see how important the milk supply is, yet it is frequently omitted. You can see that if three or four cases of typhoid occurred on the route of the same milk dealer, they would attract instant attention and would demand precedence in examination, but the same three or four cases might not get correlated for some hours if the name of the milkman should be omitted from one or two of the cards.

Thoughtfulness on the part of physicians is important, since they are on the ground some time before it is possible for the public health officials to have information of any kind. There are things that a thoughtful man can do that may prove of service; for example, to select an obvious one, to immunize other children in a family in which diphtheria is found.

Early notification of births is another important matter and failure to give it at all is the weak link in the registry system in the country. If there is any thing in which American physicians in general need to be spurred on to their plain duty, it is in the notification of birth. As a matter of fact, this country, priding itself on its intelligence and its advancement, is practically without birth statistics. Chicago gets perhaps 65%, and Baltimore less than 45, while whole districts are exceedingly deficient. Such a condition of statistics is not creditable.

Boston is so much better than so many places, with its estimated 95% registered, that it might seem as if nothing further is to be said, the more so since it is estimated by the registrar that the registry of births attended by physicians is only 1% short. The recent school rule requiring birth certificates for all new scholars will probably make this small deficiency still less.

But in the advancement that leads to such good total percentage of registration, new chances to improve the public health open, and Boston can better its general health through bettering the health of its infants by quicker notification. The figure above given is that within the limits of the law, which allows the physician till the fifth of the succeeding month in which to send in his notification, but this is not nearly soon enough. If infantile blindness is to be prevented, the treatment must come immediately after birth. The physician who delays his notification runs risks for the child. It is well known that such things as the ignorance or carelessness of mothers is responsible for many infants' deaths. The whole infant situation would be bettered enormously could there be immediate inspection of the child and a proper system of education for the mother. It is as easy to send a birth notice from the letter box at the corner before visiting the next patient as it is to send it a week or two later, and this promptness is being more and more recognized as an essential factor to good health. And there is more in this than merely the infants' lives. Newsholme has traced, you will all remember, at the sanitary meeting in Brighton last month, that there is an intimate relation between the infantile mortality and the total death-rate. Everything that makes to save the lives of children of less than one year of age makes also for the saving of lives in all age periods.

It is important further to attend pretty closely to all kinds of registering that are required. The value of the statistics depend, in part, upon the faithfulness of the physicians in the different localities. To-day it is out of the question in the United States to make comparisons statistically of one city with another save during the limited times that an official census covers. Indeed, it is not always easy to compare the statistics of a city at different times with one another. The influence of a local society may be limited, it is true, to its own domain, but its example is never lost on similar societies. I think it perfectly possible for a society like this to bear a hand towards the raising of the statistical moral tone in other places. It is to be regretted that this tone is so low in this country, for statisticians must, perforce, be men of intelligence, but it is true beyond the question that commercial aspects of health figures are considered and eliminations are made for the benefit of the place, which hopes to attract trade or travel on account of its healthfulness. I question whether any medical society in the country has raised its voice against the immorality of "boosted" population figures or incomplete or manipulated returns on which the published rates are based. America has much to learn towards the improvement of its vital statistics, and societies like this can help greatly in establishing a healthy statistical tone in the community.

Incidentally I may say that there is much to be done in the way of unification of matters relating to the health. There is much need of the standardization of many factors. No two health reports in the country present the same data or in the same form, and it is often very difficult to find in a report the figures that another report will blazon forth on the first page. There is much looseness in terminology, many differences in spelling, while specialists delight in the use of the newest terms in their own divisions, which may readily not be

in the Bertillon list or in the latest of medical dictionaries. There is very much to do in the way of such standardization, but it is a minor matter compared with so many others that I will not argue it just now.

Isolation is another important matter wherein physicians need a good deal of education. The child is well to the eye of the parent; he feels his confinement and is restless; he is anxious to get out of doors, to play with his fellows, but the time that experience has shown to be within the danger line to others from him has not passed. Pressure is brought to bear upon the physician, and he in his turn seeks to have the isolation terminated. The officials are firm, and there is ill-feeling and the authorities are declared to be arbitrary.

Now this is all a matter that ought to be pretty easy to determine, for the time for isolation for the different diseases ought to be well established and the symptoms known that suggest the release. If these things are wrongly figured, then by all means establish some other and more correct standard, but whatever may be the standard that medical authorities establish, let the individual physicians observe it. A society like this, by discussing such matters, by bringing the reasons to the attention of the physician, will give him an artificial backbone if he needs it, or may perhaps show him in a different light the righteousness of the conventional proceeding and make him see for himself the propriety of isolation to the agreed-upon limit.

So much for the higher education of the physician. Let us turn our attention for a few moments to matters in which the physician may help in the education of the people. One important side of this work is necessary because the public is quick to acquire ideas of certain kinds. There is an inherent fear of epidemics, and on the slightest pretext the people are alarmed and a panic results. Only this week there has been voiced at a meeting in Boston a plea that physicians shall bear a hand in allaying the panic over infant paralysis. There are similar occasions from time to time over diphtheria and other diseases. A calm and authoritative statement by a medical society circulated by the physicians and the press would be all-sufficient to induce the return of a sane and reasonable condition of the public mind.

One of the matters in which the information of the public will presently be necessary is disinfection. To the layman, it is the outward and smellable sign of a process of purification, and wherever the odor of its chemicals is to be detected, there is faith in a good work going on. From the brick that wastes away in a couple of months to the more formidable formaldehyde processes, the "disinfectants" come in enormous variety. For most of them undoubtedly soap and elbow-grease would be a more efficient substitute. The practise of disinfecting rooms and large spaces after sickness has grown up and is much in vogue. Is it necessary and effective, or is it, like sewer-gas, a relic left by the wayside by knowledge in its progress? It is costly; should it be used in selected cases? Here is a matter that is now in the air, and the balance seems to be settling against the large use of the process in rooms and houses. It is expected by the people, and if it is no longer useful, the people must be informed. Is it not a duty, in these advanced times, of a society like this to foresee the situation? It is in a position to catch the whisperings, and it might gather the threads of information, and, if a change is coming, it could help spread the news.

And in the same category is the typhoidal oyster. Fear of germs has robbed thousands of our citizens of a delectable food. For years no one has hinted otherwise than that the oyster and typhoid fever were linked in unquestioned brotherhood. At this moment the balance is turning, sanitarians are looking at the facts and questioning any real relationship save in a very few extraordinary instances. It is due to the people, when the time is ripe, that the decision, whether affirmative or negative, be given to the world in an authoritative way. Not by any mere paragraph in the newspaper picked up by the reporter or his necessarily hasty and superficial digest of a technical report, but by plain statements in plain English, backed by the name of a well-known medical society.

And as for the "typhoid fly," he has had a remarkable and sensational run in which medical men and bacteriologists have not hesitated to make of him a scapegoat and pile on his back all the ills that flesh is heir to. But I do not believe that in a well-sewered city, disposing fairly well of its sewage, he cuts much figure in the dissemination of disease. Perhaps some tuberculosis may be carried by him here. But although I speak of the fly in this way, I am not taking his part, for he is a filthy beast equally at home in dining-room or muck-heap, and carrying the filth of street or alley to the food. Get rid of the fly by all means, but not under false and sensational pretenses. Fight him for what he is, a filthy nuisance.

Two most important technical processes related to public health are vaccination and animal experimentation. The former has its inveterate enemies who leave no stone unturned to oppose it and succeed in enlisting under their standard bodies of medical agnostics and even medical anarchists, so that together a good numerical showing can be made. Hardly a year passes without some anti-vaccination bill presented to the legislature. Usually The Massachusetts Medical Society presents a speaker in its defense, but in my opinion a much better showing should be made. In these enlightened times it would seem as if so evident a matter needed no backing, but the fact remains that there is an aggressive and persistent opposition which may best be met by an equally active support.

In all probability there is no other subject in medical work that is less well understood by the people than animal experimentation, which is always opposed by bitter antagonists, who are able to draw on the sympathies of tender-hearted

people and secure their support. The unfortunate name that has for years been attached to it is against it from the point of view of the people. With the possibility of such an exhibition as that recently on view in New York City, said by those who have visited it to be inaccurate in presentation and misleading in deduction, medical societies should take it to heart that animal experimentation is to-day in need of all the support it can get. It would be unfortunate to have a law passed in our state forbidding the use of animals for experiment, including the diagnostic work, yet such a condition seems by no means beyond the bounds of possibility. I am of the opinion that such societies as this should be heard, and with no uncertain sound whenever opportunity permits, when so much is dependent and the opposition can present so formidable a front. Then through the members a proper view of the science can be given authoritatively to the people.

Now there are a goodly number of things that will benefit the public health all about us, in which public opinion must be formed. The drinking cup has been abolished in Massachusetts. It was not because any medical society recognized the danger and asked for the abolition, but purely through other influences. Medical men, of course, gave their opinions, but, as a matter of fact, the movement followed by some months or a year such a movement in the West. It is rather too bad that it could not have originated here, and it would have if there had been strong, influential medical societies interested and active and realizing the importance of the change.

There are a number of improvements of this kind that the country needs. For myself, I can think of no sanitary abomination more in need of reform than the railway closet. One can hardly credit that in a civilized community we have permitted it to exist so long, yet it is only the occasional individual voice that is raised against it. Its dangers are not unknown, for at a few localities the doors are locked while passing over some watershed that is used for the supply of a city. Let me picture it for you: A little box, probably unventilated unless by a window, which modesty seldom permits to be opened. No water flushes the hopper, which retains its filth perhaps to the end of the journey. The dejecta fall to the roadbed below, or catch on the chains by the way and by ingenious devices like this are spread far and wide. No water is convenient with which to wash the hands that not unlikely have come in contact with infectious matter. Just outside the door, on whose handle perhaps a few germs are left for the benefit of the next comer, there is the water tank. The individual fresh from his devotions to Cloaca grasps the handle — more germs — and drinks from the universal cup, if he be outside of Massachusetts or Kansas. I do not need to say another word, gentlemen. The railway closet, distributing its wastes over miles of roadbed, must go, and I think you are the kind of organization that can soonest make it go.

I wish for a moment to refer to a matter which it seems to me is worthy of attention as affecting the health of the larger communities of the country. In the superficial glance that I have been able to give over the sanitary needs of the country I have been particularly struck by the seeming lack of the study of tropical disease. This would seem to be one of the more important gaps in medical work in the country, where year after year some new foreign disease from the warm latitudes is found to be homed. There is pellagra and the hookworm, and no one knows what may be the next one to be found well established. With the present state of knowledge on the part of general practitioners, the chance of diagnosing such ailments, even in institutions, is not large, yet the discovery of the cases is important. It is very true that the unsewered and even un-outhoused condition of the South has given opportunity for parasites to make hosts of a barefooted people to an extent that in the North will probably never be possible, but the facts show that there has been much unrecognized tropical sickness in the countries of outdoor life, and if present conditions continue there will be much more. This is a living question of the near future and one that societies of this kind can well take up, for it involves large questions in matters pertaining to the education of the physicians who in their distribution over the country must infallibly come into contact with imported and ordinarily unfamiliar disease.

One cannot close the story of what societies and physicians stimulated by their associations can do for the education of the people without a word about sex hygiene. The false modesty precluding public mention of this matter, which has prevailed far back of the memory of any one here present, seems now to be on the point of giving way. Public-spirited men and women are leading the movement to present definite and trustworthy information in lieu of the older method of dissemination on the street corners with the air of secrecy by those who had no right to be teachers. To-day it would seem as if it is the layman who is in the forefront of the work. Does not this belong to the physician, fitted by his training and by his knowledge of the nature and extent of the dangers?

And directly in the matter of specific disease, there seems to be an important place for the physician as a public educator. He is not likely to take the initiative unless there is behind him the confidence and support of his confrères. A society furnishes these elements. And further still, although the enormous consequence of such diseases in the morbidity and mortality of the community is acknowledged, and although means of treatment have been devised, there is still to be worked out the practical way of presenting the whole matter to the people. This will, of course, be eventually worked out by the cut-and-try method that has in the past built up the sanitary systems. But are we not in another age? Is it not time to work in quicker fashion? Is there not here an opportunity for the many minds of a society, or, in fact, of many societies, to focus

themselves on the problem and reach much more easily the methods that shall be of the quickest benefit to man?

And last of all there comes the question of the attitude of medical men towards the press, which is a matter for which the time is ripe, I think, for consideration. With the insistent progressiveness, not to say inquisitiveness, of the newspaper, and its resources, and the conservativeness of the physician, it is an irresistible force meeting an immovable body. But I do not believe the situation quite so desperate, and think that a society like this is thoroughly competent to discuss the subject and to arrive at a ground where the essential matters of consequence in medical discovery may be given to the people in an interesting and trustworthy manner.

EXPERIMENTS ON TRANSMISSION OF BACTERIA BY FLIES WITH SPECIAL RELATION TO AN EPIDEMIC OF BACILLARY DYSENTERY AT THE WORCESTER STATE HOSPITAL, MASSACHUSETTS, 1910.*

BY SAMUEL T. ORTON, A.M., M.D.,
Pathologist to the Worcester State Hospital; Assistant in Neuropathology, Harvard Medical School;
With the assistance of
WALTER L. DODD,
Student in the Massachusetts College of Pharmacy, Boston, Mass.
(Working in the laboratory of the Worcester State Hospital during August and September, 1910, by courtesy of the Superintendent.)

THIS investigation of an epidemic of bacillary dysentery at the Worcester State Hospital occurring in July and August, 1910, has been approached to first ascertain the causative organism;

*Read in part before the Boston Society of Neurology and Psychiatry, Oct. 20, 1910.

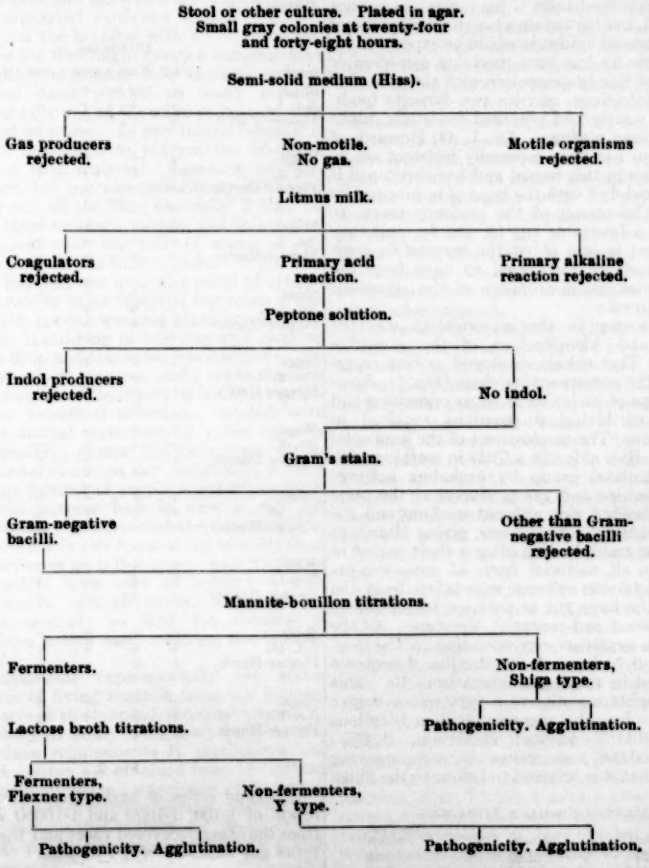

FIG. 1.

second, the method of transmission from case to case, and, third, prophylactic measures against such transmission.

Our epidemic, consisting of 136 cases, resembled in type of incidence and spread that of the Danvers State Hospital, Massachusetts, 1909. The incidence was gradual and the spread scattering and irregular, no one ward or set of wards suffering in marked disproportion. This lack of the explosive type of outbreak applies against the theory of a water supply infection. The hospital receives its water from the Worcester city supply and such a source of infection can be practically ruled out by the lack of concomitant outbreak in the city. Milk infection may also be excluded on the grounds of lack of explosive incidence and by the fact that only certain of the diet cases receive raw milk and that no apparent relation exists between those on a raw milk diet and the cases infected. The infection of raw foodstuffs, i. e., vegetables, cannot be excluded, but here again a heavier incidence and more widespread epidemic would be expected.

The house fly has been receiving considerable attention of late in connection with the spread of intestinal infections, and its two favorite foods, i. e., fecal matter and prepared foodstuffs, make it a dangerous medium. Dr. L. O. Howard, of Washington, has been especially insistent on its potentialities in this regard and has christened it the "typhoid fly" with the hope of impressing its danger. The season of the epidemic seems to have been a favorable one for the fly, and they were present in and about the hospital in great numbers and are considered to have been the chief cause of the distribution of the organisms from case to case.

The first step in the investigation was the isolation and identification of the causative organism. The technic employed is best represented by the accompanying chart (Fig. 1), showing the steps of exclusion of other organisms and the data of biological reactions required in identification. The employment of the semi-solid medium of Hiss aids not a little in working with all the intestinal group by excluding actively motile organisms and gas producers at the same step. It also is a rich nutrient medium and the growth is usually a heavy one, giving abundant material for transplanting after a short period of growth. In all, material from 15 cases was examined. In 5 the cultures were taken from the lesions of the large gut at autopsy, in the others from the blood and mucus of the stools. Of the 15 cases an organism corresponding to the morphology and biology of the Bacillus dysenteriæ was isolated in varying numbers from 10. This organism splits mannite to a very minor degree as shown by the mannite-bouillon titrations (average, 0.11% acidity; maximum, 0.30%; minimum, 0.00%, as shown in accompanying chart), so that it is believed to belong to the Shiga type.

MANNITE-BOUILLON TITRATIONS.

Case.	Control.	Mannite.	Per Cent. Acidity.
1	2.30	2.40	0.10
2	2.32	2.37	0.05
3	2.10	2.13	0.03
4	No B. dysenteriæ recovered.		
5	2.00	2.30	0.30
6	No B. dysenteriæ recovered.		
7	No B. dysenteriæ recovered.		
8	2.31	2.40	0.09
9	2.32	2.41	0.09
10	2.26	2.37	0.11
11	No B. dysenteriæ recovered.		
12	No B. dysenteriæ recovered.		
13	2.30	2.30	0.00
14	2.32	2.41	0.09
15	2.19	2.43	0.24

The results of a parallel series of agglutination tests give evidence that the organism belongs to the Shiga type (Fig. 2). These tests were made with the blood of a recovered case and are parallelled in each instance with a test in the same dilution of a stock Shiga and a stock Flexner-Harris type.

The second point of attack was an effort to find some tangible evidence of the mode of transmission. Recent literature on epidemiology is convincing of the point that the fly is a factor to be considered in the spread of the intestinal diseases, especially in those epidemics where the incidence is gradual rather than explosive and the cases occur here and there throughout a neighborhood or in separated wards of a hospital.

A survey of the hospital with a view to determining how the flies might become contaminated with dysentery organisms from carriers or from unrecognized cases yielded so many possible sources that only one of the more prominent ones was selected as a test. In any insane hospital it is well-nigh impossible to prevent the access of flies to some fecal material. Screening methods are of value, but are also notoriously inefficient in keeping out all the flies, especially if they be present in large numbers outside, and this factor, in conjunction with the filth of many of the patients in such an institution, makes the problem an almost hopeless one from this point of attack. At the Worcester State Hospital one room of the laundry with special washing machines is given over to the laundering of bedding and clothing soiled with filth, and this room was selected as one of the most prolific sources of fly contamination with fecal material. The reports of bacillus carriers in all the intestinal infections, coupled with the almost annual occurrence of a few cases of severe dysentery, render the occurrence of infected material in almost any assortment of feces from a large number of people so readily possible that for the purpose here in view it was not deemed necessary to show that there was actually material present in this room of the laundry from either a carrier or an active case. As a matter of fact, the active cases were all isolated in well-screened wards, and all stools, bedding, etc., disinfected carefully so that the chances of material from active cases reaching the laundry were small.

To demonstrate experimentally the actual transference of living bacteria from the laundry to other parts of the hospital, recourse was had to a non-pathogenic easily recognized bacillus, and to fulfill these requirements B. prodigiosus was chosen. A culture was obtained from Dr. Arthur M. Worthington, of the Department of Bacteriology of the Harvard Medical School, and we wish here to express our thanks therefor.[1] Bouillon cultures of B. prodigiosus were exposed on a high shelf in the laundry room above mentioned, on sterile gauze pads in sterile china saucers, and renewed daily during the experiment. Sterile wire fly traps baited with sterile sugar syrup were then set in a number of wards and the scullery room off the kitchen and each day's catch taken to the laboratory and allowed access to a surface of agar in a large crystallizing dish. These fly plates were then kept at room temperature and observed at twenty-four, forty-eight and seventy-two hours for the occurrence of red colonies. Fig. 3 gives an idea of the relation of the laundry room to the kitchen and wards and indicates the place of planting and wards from which flies were taken for examination. All of the saucers after exposure for twenty-four hours were found to be heavily fly-specked, and to make a rough estimate of the number of flies which had visited the plant and were in all probability contaminated, the specks on one were counted. The count resulted in the figure 115 for one plate for a twenty-four-hour exposure. Some observation of the fly while feeding has shown that while many flies defecate while feeding, the majority do not at any one meal. Of a number watched, it was found that only about one out of six defecated during their meal, so that the 115 specks, excluding a second trip by individual flies, may be taken to very roughly mean 690 flies which visited the bait and probably become contaminated with B. prodigiosus in twenty-four hours. The plants were renewed in six days, so that in all, on the above estimate, about 4,000 flies may be assumed as carrying the organism. These figures are not given as at all accurate, but merely a deductive estimate of the number exposed.

The results were striking. The first plant made in the laundry was on Aug. 24 and on the 25th flies were taken in a sterile net from the laundry and scullery room of the kitchen. Plates from both of these catches were rapidly overgrown by a spreading organism and had to be discarded. On the 26th, however, two days after the original plant, plates from flies taken in traps in both the kitchen and in the nearest ward dining room, Lincoln 1, showed unmistakable prodigiosus colonies. From the kitchen trap 18 flies were taken, and the plates showed three positive colonies. The Lincoln 1 trap yielded 19 flies and the plates two positive colonies.

On the 27th, the third day after the first plant, plates from flies trapped in Lincoln 1 and Folsom 2 both yielded prodigiosus colonies. The Lincoln 1 plate was made from a catch of 17 flies and showed four positive colonies. Only three flies were taken from the Folsom 2 trap, but of the colonies resulting, one was a prodigiosus.

On the fourth day of the experiment the remaining two wards from which daily catches of flies were made showed the test organism. Thayer 2 represented by ten flies showed three positive colonies, while Phillip 4 gave a plate which was dotted over here and there with almost as many prodigiosus colonies as those of other kinds. This result was so out of proportion to the other findings that it was repeated on the 30th, and on the

[1] We wish also to thank Dr. B. L. Arms for some chromogens which he furnished, but which were not employed in the experiments.

same day a trap was set for the first time in another ward, Salisbury 1. The plate from Phillip 4 on this day made by 12 flies yielded five positive colonies, which is more in accord with the other results. The Salisbury plate from 17 flies showed three colonies of prodigiosus. The very heavy growth on the plate from Phillip 4 on the 29th may have been a result of contamination of the syrup bait by one of the earlier caught flies and a consequent tracking in by later catches. This factor, of course, cannot be excluded in any of the traps, but the mere presence of B. prodigiosus in traps which were sterilized before each setting and baited with sterile syrup gives evidence of the presence of at least one fly which had visited the laundry unless by this time the spread of the organisms from the original plant with consequent growth in other places might have given new sources of supply from which organisms could be carried.

The fact remains, however, that the organism was recovered from the kitchen and from every one of the five wards in which traps were set within six days from the original plant, and while growth in the syrup bait contaminated by an early entrant or growth, in other places than the laundry, planted by flies from there and relayed by other flies to the wards, might preclude any quantitative conclusions, the qualitative results are unaffected.

The appended chart, Fig. 3, gives an idea of the relation of the various points of recovery to the original plant and serves to emphasize the tremendous bearing such bacillary fly transmission may have on any of the intestinal diseases and, in fact, in many other infective processes. The dated crosses in the laundry represent the time of planting and renewal of the original culture. The dated empty circles represent the traps set which yielded negative results. The dated circles containing crosses indicate the traps from which flies were taken which on culture showed B. prodigiosus. Approximate distances are indicated on the diagram.

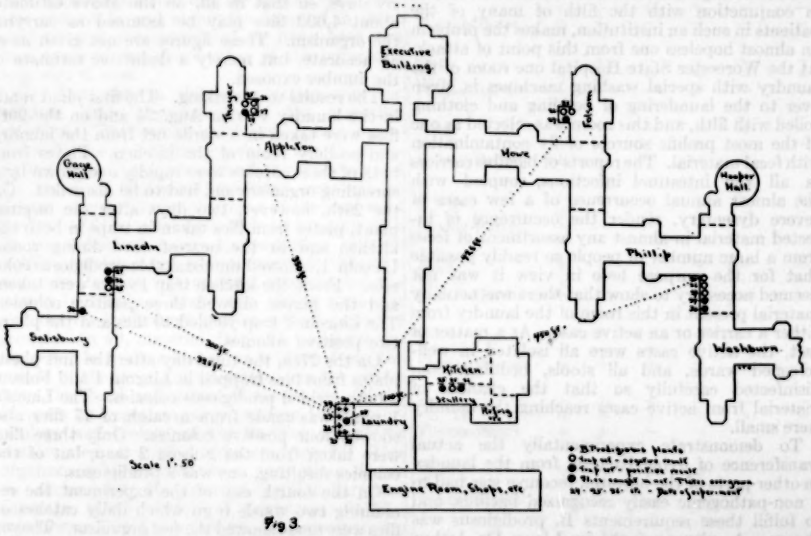

Fig 3.

The third line of attack aimed at prophylaxis against the fly's activity as a transmitter, and the subject permits of three methods of approach. First, Keep the flies away from all fecal matter; second, Keep the flies away from all foodstuffs; and third, Eliminate the fly.

The first method, that of keeping the flies away from fecal matter, is nowadays attempted in almost every institution or large community by the proper disposal of sewage, but the problem in institutions for the care of the insane is rendered so much more difficult by the filthy habits of many of the patients that such sources cannot be prevented even with the best of care and training of nurses and attendants. It may be well to emphasize here, however, the great importance of doing away with all the removable sources of such contamination and of screening all places where fecal accumulations are unavoidable so as to reduce, as far as possible, the danger by this means.

The second method, i. e., keeping the flies away from the food, is also tried almost everywhere by the usual screen and fly-paper method, but with anything but satisfactory results. The ease with which flies, when present outside in great numbers, find entrance to a screened room is remarkable, and little can be expected from this method in seasons when the crop is large. All of the ward dining rooms of the Worcester State Hospital are

thoroughly screened and yet all of the flies used in the prodigiosus experiments here reported were caught in traps placed in the dining rooms.

The third method, eliminating the fly, promises much better, however. Dr. L. O. Howard, in the bulletins of the Bureau of Entomology, Department of Agriculture, calls especial attention to the frequence of horse manure as a breeding place of the "typhoid fly," as he has called it.

He quotes the work of Newstead, in Liverpool, and Forbes, in Illinois, as proving the breeding of flies in spent hops, ash pits, paunches of slaughtered cattle, tallow vats, miscellaneous garbage, etc., but states that commonly the eggs are laid upon horse manure.

Howard has found that in Washington the female fly lays about 120 eggs and that ten days are required for the larval and pupal stages. The egg hatches in eight hours after it is laid and the young larva molts at the end of the first day, again at the end of the second day and enters the puparium stage at the end of the fifth. Five more days are past in the chrysalis stage, and at the end of the tenth day the adult issues.

The Worcester State Hospital, like practically all such institutions, stands in the center of fairly large grounds, and the absence of any probable neighboring fly source renders the problem of elimination easy of approach. Under such conditions the fly crop can be considered as practically all home-grown, and care of the breeding places in such surroundings ought to result in a great reduction if not the ideal condition of elimination of the fly.

With these considerations in view, a survey was made of the grounds to identify the chief breeding places. This is an easy matter, as a rule, as the maggots and puparia are readily found in great numbers in places suited for their growth. That the fly produces maggots is a fact recognized by every one, but the converse, i. e., that the maggot is necessary to produce a fly, seems to have received less acknowledgment. One hears quite frequently the remark that the flies are breeding in a building, but a question as to the presence of maggots in such building is generally sufficient to point out the error.

The search was first applied to the horse-manure piles following Dr. Howard's findings. There are only two such accumulations on the hospital grounds. One, at the stable, is in a large masonry pit which is drained below and covered so that, while it is not fly-proof, it is dark and dry. An afternoon's search through this pile with a pitch-fork failed to reveal a single maggot or puparium, while it did show that the manure was molding or heating rapidly. A subsequent examination of two other piles away from the hospital where the manure was kept dry and in the dark showed the same condition of rapid heating and molding and the same dearth of fly larvæ. The second horse-manure pile on the hospital grounds is at the farm barn. Here the manure is dropped through floor traps and when a pile has accumulated is taken to the part of the barn where the cow manure is collected and mixed with that. Here were found a considerable number of larvæ and puparia, but they were by no means in numbers sufficient to account for the swarms around the buildings. The larvæ were found more frequent in that part of the pile consisting of pure horse manure, while, as the other end of the barn was approached, where the proportion of cow manure was higher, the number of maggots was noticeably less until the pure cow manure was reached, where the larvæ were very few. This finding accords with Howard's statement that while the house fly will oviposit on cow manure, he has never been able to rear it in this substance, and also suggests that if horse manure be mixed with a sufficient bulk of cow manure, its efficiency as a breeding place for the house fly will be lowered at least, and possibly the breeding may be entirely prevented in this way.

Having, then, practically excluded the two horse manure piles, the search was extended. The pigpen was next examined and here was found a condition more in accord with the numbers of flies, though hardly sufficient by itself. The piles of pig manure mixed with the straw bedding, etc., were kept outside the piggery building and exposed to the air and rain and were found to be badly infested.

One ounce of this material was taken from a point a few inches below the surface where the chrysalides were thickly clustered, and from it were taken 868 puparia.

Another prolific source was found in piles of spent hops and barley malt, brewery waste, which had been hauled in for use as fertilizer. The hops show a tendency to mold rapidly and apparently do not favor the breeding of the fly as does the looser barley malt. This material proves an excellent food for the larvæ, and in those parts of the piles where there was an abundance of moisture the maggot content was astonishing. One ounce from the richest portion of one such pile yielded 1,018 maggots. The first observation of these brewery waste piles was made at a time of the summer when there had been considerable rain and the piles were damp throughout, while in places the material was well saturated. At one place where there was a layer six or eight inches deep of soggy barley over the ground the mass was simply crawling with maggots, while a visit after six days of continued dry weather showed that this layer had dried out fairly well and that the maggots had practically all disappeared, and the puparia which were found in the neighborhood were by no means numerous enough to account for all the larvæ previously seen. I take it that this means that a large proportion of moisture is required for the greatest activity, and would suggest the experiment of roofing and draining such piles to determine whether they might not thus be kept until such time as they are needed for spreading and yet rendered innocuous.

Spreading on the ground, or, better, plowing in, of all vegetable waste seems the easiest method of caring for such material, and where these methods are followed once a week, so as to allow no accumulation to stand long enough to hatch

its quota, the nuisance ought to be well in check.

Howard has experimented with the treatment of manure piles to stop the breeding of flies, and his conclusions are that chloride of lime in the proportion of one pound to eight quarts of manure makes an effective treatment. His method is to keep the manure in a closed bin or receptacle and sprinkle each day's accession with a small shovelful of chloride of lime and to have the bin emptied every week for distribution on the gardens, etc.

In order to make a rough comparative estimate of the degree of activity of the fly in the various breeding places, one pound of material from each was taken to the laboratory and kept in screen-covered glass jars to await the hatching. Immediate counts of the larvæ and pupa would probably have given more accurate results, as the media varied in their reactions to the lack of moisture, and probably all of the figures are lower than would have been the case had the material remained undisturbed in the pile. By keeping the manure, however, for the ten-day interval, the flies hatched could be observed in order to form an estimate of the proportion of the house fly — Musca domestica — to the other species reared in the various media. In each instance the sample pound was taken to represent as nearly as possible the average content. The results were as follows.

Source of material.	Musca domestica	Other species.
Stable manure pile,	0	0
Farm barn, horse end,	77	0
Farm barn, mixed,	19	1
Farm barn, cow end,	1	3
Piggery manure pile,	361	5
Spent hops,	129	1
Barley malt,	539	2

The identification of species was carried no further than an observation of size and general appearance, and a determination of the presence or absence of flattened mouth parts.

Though these figures cannot be given as exactly representing the probable output per pound, yet they show the preponderance of the typhoid fly over other species and speak strongly for the necessity of cleaning out all such breeding places. If the house fly can transmit a culture of B. prodigiosus within six days to the screened dining rooms of as many wards, and if one ounce of vegetable waste can contain 1,018 maggots, it will certainly prove worth while to take care of the tons of such material which are apt to be found at any such institution which has not undertaken a fly extermination crusade.

Conclusions. An organism conforming to the Shiga type of B. dysenteriæ was recovered from 10 out of 15 cases examined.

B. prodigiosus planted in the laundry was recovered from flies caught in traps in the scullery and five screened ward dining rooms at an interval of from two to six days after the original plant.

It proves impracticable in most insane hospitals to keep the flies from access to fecal matter and from food when they are present outside in large numbers and, therefore, the best prophylaxis against fly-borne epidemics is in cleaning up the breeding places of the fly to reduce its numbers or eradicate it.

The typhoid fly — Musca domestica — breeds in tremendous numbers in decaying vegetable waste of varying sorts, and a search for maggot-infested places with subsequent attention thereto offers the best line of attack.

The house fly's egg to adult cycle is ten days, so that vegetable waste should be cared for at least once a week during fly season.

Horse manure may be treated by chemical means, but it is probable that, if it is kept dry and in the dark, but little breeding will take place. Mixing with many times its bulk of cow manure may prove effective.

When possible, all waste material should be plowed into the land without accumulating. Spreading over the land will probably suffice to reduce the pest markedly.

In hospitals surrounded by considerable ground it is probable that the great majority of the flies are home grown, and the extermination of their breeding places is an object which cannot be overlooked.

REPORT OF A STUDY OF BROWN-SÉQUARD'S EPILEPSY IN THE GUINEA PIG.

BY A. E. TAFT, M.D.,
Research Officer, 1909–10, Monson State Hospital, Palmer, Mass.

IN general, epilepsies are classified as idiopathic and organic, the former to include those cases where no cause is known, and the latter those in which a definite pathogenesis is found. Post-mortem findings may reveal conditions not recognized during life. Of the cases coming to autopsy at this hospital, e. g., from April, 1909, to August, 1910, 54% show gross lesions associated with the nervous system. Since epilepsy in the guinea pig is organic in type, and the course and severity of the disease may be controlled as it cannot be in the human subject, the study upon which this report is based was taken up and carried on in detail.

First in 1850,[1] and in subsequent papers,[2,3,4] Brown-Séquard published his observations on a condition which he had found following various injuries to the spinal cord or to the sciatic nerve of the guinea pig. This was a tendency to convulsions which he considered analogous to epilepsy in man. The convulsions might occur spontaneously, but more often could be induced only by irritation of the skin over a definite area on the face, neck and shoulder, corresponding to the side on which the cord or nerve was injured. Trophic changes and anesthesia of the "epileptogenous zone," increase in nasal secretion on the affected side, and occasionally corneal affections, were reported as accompaniments of the convulsive condition.

A further observation, and one which has been extensively cited as demonstrating the transmission of acquired characteristics in mammals, was the observation that the young of epileptic

animals might themselves become epileptic sometime after birth. But the fact has not been generally emphasized, that the so-called hereditary cases never occurred apart from other abnormality.

Brown-Séquard himself says:[5] "This inherited epilepsy I have never observed in other animals than those which had also inherited absence of toes." In the work of Charrin[6] and Prévost,[7] both found that simple amputation of a part of an extremity resulted in the development of the epileptic attack. There seems here to be a possibility that the deformity in the offspring in Brown-Séquard's cases was due to pre-natal or very early post-natal injury, bringing about a condition which would produce the same result as simple amputation of part of an extremity. The work of Brown-Séquard has since been repeated, in part at least, by a number of investigators,[8,9,10,11] some of whom have been able to confirm many, but not all, of his findings, and this question of transmission has been one of variance.

The work of this report was undertaken to observe more particularly the transmission from parent to offspring of the "epileptic" and associated conditions. It has been continued during a period of eighteen months, and is based on observations made on 195 animals. Of this number, 68 were subjected to a lesion of the sciatic nerve. The remainder were the normal animals used, and the succeeding generations. They were mainly the common smooth-haired variety, though a few rough-haired angoras were included. A large, light, well-ventilated basement room was used for their quarters, and cages of one-half inch mesh wire screen 13 by 18 by 18 in. were made for this special purpose. The frame of the cage was of zinc, and a zinc tray was made to slip in and out of the bottom of the cage in drawer-fashion to aid in cleanliness. The front was hinged to form a door, and half of the top could be lifted to admit food if desired. Sawdust was used in the bottom of the cages, and these were given weekly thorough cleanings, the tray being washed out with Sulpho-napthol and abundant hot water. The principal food was hay, or green grass in summer, oats, and carrots or beets. With four or six animals in a cage, quite a large number may be kept clean and comfortable in a relatively small space and can be conveniently arranged.

In carrying out the work, the following points have been particularly considered:

I. The requisite injury of the nervous system.
II. The development of the scratch reflex.
III. The development of the convulsion.
IV. Age relation to time of development of the convulsive tendency.

IX. Summary.

I. THE REQUISITE INJURY.

It has been well demonstrated by Brown-Séquard[1,2,3,4,5] and others,[8,9,10,11] that various injuries of the cord or larger nerves result in the possibility of exciting convulsions by stimulating certain well-defined areas of the skin. Resection of the sciatic nerve was chosen in this case as it causes less disability in the animal and produces almost unvarying results. Both nerves were divided in 55 of the cases, and only one in the remaining 13.

The neurotomy was in every instance done under full ether anesthesia, the entire operation requiring hardly more than five minutes after anesthesia was established.

The technic was as follows:[12] An incision about 1 cm. in length was made just behind the great trochanter and carried through skin and muscle. The sides of the incision being drawn apart, the nerve is seen as a glistening white band which can be elevated and divided. Resection rather than simple division was done to prevent reunion of the approximated ends. A single stitch suffices to close the wound, which heals immediately. It can be scarcely detected on the second day.

II. THE SCRATCH REFLEX.

After a period varying from five to thirty-three days, the average being eighteen days, following the division of the nerve, there develops, on irritation of the specific zone, a rhythmical scratching movement with the hind leg of the corresponding side.[14] This appears to correspond quite definitely with the scratch reflex in the spinal dog described by Sherrington.[15]

"In the dog, when the spinal cord has been transected in the neck, the scratch or scalptor reflex becomes in a few months prominent. A stimulus applied to any point within a large saddle-shaped field of skin excites a scratching movement of the hind leg. The movement is rhythmic alternate flexion and extension at hip, knee and ankle. Each flexion recurs at a frequency of about four times per second. The stimuli provocative of it are mechanical, such as tickling the skin or pulling lightly on a hair. The receptive nerve endings which generate the reflex lie in the surface layer of the skin about the roots of the hairs."

The body is bent with the convexity away from the affected side and the scratching foot approximates the point irritated. The foot movement continues only during the time of irritation. This phase probably represents what has been termed by some the incomplete convulsion, but differs quite definitely from the complete attack of which it always forms a part.

III. THE DEVELOPMENT OF THE CONVULSION.

In this series, the complete convulsion developed in periods varying between ten days and three months and seventeen days, the average being one month and nine days after the division of the nerve and averaging eighteen days after the appearance of the scratch reflex. In the beginning the attack is usually very brief. On irritation the scratch-reflex first appears and the animal falls on the side with the eyes closed, only for an instant, almost immediately gaining its feet and appearing quite normal. Of the 68 animals operated upon, only 2 failed to develop the complete convulsion. These were black and tan angoras, a female and an offspring. Division of the nerve was first done on the older animal on Sept. 17, with no result. Consequently the operation was repeated and was done also on the younger, on Jan. 4. The older showed the typical trophic changes, with development of the scratch reflex on Jan. 28, the younger not showing the reflex until March 1, and neither has had a complete convulsion during the period of six months subsequent to operation. Thus 97% developed the complete convulsive attack, 3% demonstrating only the scratch-reflex.

Nowhere in the literature have we been able to find any exact statistics of the results obtained by Brown-Séquard. He says that of 67 guinea pigs in which the sciatic nerve had been cut, all except a few developed the "complete attack." Bramwell and Graham-Brown,[18] in their series on 41 animals, report that one quarter showed fully developed convulsions, two thirds the scratch reflex and one third negative. Of 100 animals operated upon by Obersteiner, almost all — which is quite indefinite — developed the complete attack.

Gutnikow, in Obersteiner's laboratory, operated on 40 animals, only 6 of which developed convulsions.

Karplus, some years later, also working under Obersteiner, among 30 animals operated upon, obtained no complete results and was obliged to give up further observations. Evidence is sufficient, however, to show that, in general, division of the sciatic nerve will result in convulsions.

IV. AGE RELATION TO DEVELOPMENT OF CONVULSION.

It has been claimed that age, judging by the body weight of the animal, determines the time of development of the convulsive tendency, and also the severity of the attack. In the series of 58 animals observed by Bramwell and Graham-Brown,[18] in which only 10 developed the complete attack and 8 of these weighed over 650 gm., "they drew the conclusion that the age of the animal at the time of the operation, as approximately judged by its weight, appeared to be a factor of importance in determining the subsequent development of the complete Brown-Séquard fit." This is probably true in a degree. That is to say, large, well-nourished animals over eight months of age do react more quickly and definitely than those in the first few months of life. Among the latter, however, a difference of a month or two seems not to be significant. Of 4 animals in this series operated at the same time, 2 were over four months of age, one was two months, and one only one month old. The youngest developed convulsions a week before any of the others and only thirty-three days after the operation. This would go to show that age is not necessarily a determinant in the development of convulsions.

V. THE ZONE OF IRRITATION.

a. Extent of the Area.

The convulsions following injury to the sciatic nerve were in no case spontaneous, but were produced by mechanical irritation of the so-called "epileptogenous" zone. This is an area of the skin covering the side of the face, neck and extending slightly beyond the posterior limit of the scapula. Light molding of the skin between the thumb and forefinger is quite sufficient to induce a reaction. More extensive manipulations or sharp pinching are not effective. In the most sensitive animals, touching the hair on the back of the neck, or holding the animal by the shoulders, will produce a convulsion. In this way, the attacks may appear spontaneous; when several animals are in a cage together, simply being brushed against serves to cause an attack.

In most cases, close observation shows the first area to become sensitive is the skin over the lower jaw and sometimes just beneath the eye on the affected side. There is apparent anesthesia at this point, and this extends progressively over the neck and shoulders, until nearly the anterior half of the body, on the side of the divided nerve, becomes sensitive.

b. Changes Occurring in the Area.

Concurrent with the beginning anesthesia and the development of the scratch reflex, there appears a trophic change in the zone of irritation. Parasites accumulate upon it; the hair becomes dry and breaks off or falls out, leaving the skin quite bare, or it may be there is only a thinning of the hair, while the outer limit of the zone is marked by a narrow band about 0.5 cm. in width where the hair is entirely fallen out. In some instances, this stripe of skin may ulcerate and slough away, followed by formation of dense scar tissue. Graham-Brown noticed that this zone became more sensitive after cessation of convulsions than the corresponding area on the opposite unaffected side. As the operation on this series of animals was bilateral in most cases, observations on this point could be made only on very few, but in these the hyperesthesia was quite apparent.

VI. THE CONVULSION.

The first step in the production of a convulsion is the irritation of the "epileptogenous" area. This excites the scratch reflex, which always precedes the complete convulsion. In this phase, the body is curved toward the irritated side, the hind foot approximates the point irritated with a rhythmical scratching movement and the muscles

in the back of the neck are contracted, raising the nose above the plane of the body. After from six to ten strokes of the foot the animal falls on its back with the eyes closed and all muscles in a state of tonic contraction, the thorax is fixed and the legs flexed. Following this there is clonic spasm of the extremities, especially noticeable in the forelegs and feet; the head is drawn from side to side; the lower jaw is rapidly lowered and raised with a sharp biting action and the abdominal muscles contract and relax, causing alternate flexion and extension of the body. Recovery from a single convulsion is almost immediate and the animal gains its feet. There is often some transient spasm of groups of muscles about the back of the neck and shoulders, or rubbing the nose with the forefeet. In prolonged attacks, periods of dullness followed. In very susceptible cases, the tonic phase may begin almost immediately on irritation, and here the animal does not fall on its back, but the convulsion takes place while in a crouching position. The single attack is usually quite brief, lasting from fifteen to thirty seconds, sometimes less. It may, however, be repeated successively many times, simulating a typical status epilepticus. One case observed passed from one severe convulsion into another, with scarcely any interval, the entire series lasting over three minutes. The question has arisen whether the complete attack is accompanied by a real loss of sensibility or consciousness as reported by Brown-Séquard. This, of course, is most difficult to determine, but it can be asserted that the animal is incapable of voluntary movements and does not respond to any of the ordinary external stimuli involving the touch or pain sense, or that of hearing.

a. Frequency.

In nearly all the animals of this series, convulsions could be elicited at any time and repeatedly, the zone of irritation rarely losing its power to bring out the reflex for at least five or six successive attempts. There were a few among the less susceptible, however, that would react only once, and then a considerable period had to be allowed to elapse before irritation would produce a complete convulsion.

b. Severity.

The severity of the attack varies widely with the individual animals. In general it is true that those which develop the convulsions most quickly show the most pronounced reaction. Mature and well-nourished animals have been ordinarily observed to be subject to the most severe attacks, which proved to be the case in this series.

c. Duration of Convulsability.

The period during which convulsions may be excited is a variable one. Brown-Séquard found them more difficult to induce after the fourth month. The average in these animals was somewhat longer. During six months, daily attacks could be produced in the greater number, and some animals were still sensitive a year after the first complete convulsions. It is to be seen that those cases in which daily or frequent stimulation has been given over a considerable period remain "epileptic" longer than those which have been excited to fewer convulsions. The state of nutrition of the animal also seems to be a contributing factor, as many that have lost in weight following the development of the convulsive tendency have also ceased to respond to irritation. Isolation and special feeding to restore good physical condition has, in most cases, brought about a return of convulsability. There appears here a similarity to the human subject, in whom restricted diet lessens the frequency of the epileptic attacks. Another very evident factor in determining the production of convulsions in the guinea pig has been the birth of young. Following this there was frequently a complete cessation, which, however, was not always permanent. This may also have a relation to the state of nutrition.

VII. THE EFFECT OF CONVULSIONS.

a. On Nutrition.

Convulsions often repeated over a considerable period of time bring about a marked general malnutrition, regardless of the abundance or quality of food given. This condition, in turn, acts to inhibit convulsability, which returns, however, on improvement of the general physical condition of the animal and is in no way influenced by the intermission.

b. On Reproductivity.

One of the most marked results of frequent convulsions is the lessened reproduction. This was also noted by Sommer [10] in his observation. These animals, ordinarily so prolific, produced so few young that, for a time, it seemed as though work with later generations would be impossible. Matters were complicated by the fact that the few young born were not alive at birth and the mother died in a day or two, showing marked emaciation. In the cases examined, cultures from the heart's blood showed a staphylococcus septicemia. This came to be so serious a matter that the convulsions were omitted, with very evidently good results. The young were born alive and strong and the adult animals lived to rear their offspring. This seemed to indicate that death following the birth of young, as well as that of the young themselves, was not due directly to the injury to the nerve, but rather occurred as a result of frequent convulsions. This was tried out further in fresh animals. The unilateral operation was done on ten young females, all of which became epileptic in course of time. These were stimulated to convulsions until the complete, severe, typical attack was assured. Following this, only very infrequent convulsions were brought on, with the result that the animals remained in far better physical condition, although there was a slight falling off, and those which bore young showed no abnormality. Here we have phenomena pointing to disturbed metabolism varying in gravity with the frequency and severity of the convulsions.

VIII. STUDY OF OFFSPRING.

The observation of the young as well as that of the adults proved a time-consuming study, as it was desired to find if any showed either induced or spontaneous convulsions. Four types were considered successively.

I. Offspring of epileptic male and normal female.
II. Offspring of normal male and epileptic female.
III. Offspring of both epileptic male and epileptic female.
IV. Offspring of animals of the second generation.

Brown-Séquard [5] reported having seen in the young of epileptic guinea pigs the development of epilepsy some time after birth, but, as already noted, this occurred only in those having a defect of the hind limbs. He could recall definitely only 13 cases of all the offspring observed in which this condition existed. He says, "Most likely what is transmitted is the morbid state of the nervous system."

Of 32 young observed by Obersteiner, 2 were judged "epileptic," but no note has been seen that there was any deformity accompanying the epileptic condition.

Westphal reports two offspring of an epileptic animal both of which on irritation of the epileptogenous zone had only an atypical attack, which, however, he considers as characteristic. This would seem to be hardly confirmatory, as many animals, both adults and young, whether offspring of epileptic or perfectly normal parents, often show spasmodic muscular contractions and body movements on irritation of the specific zone, such as twitching of the extremities and moving the body from side to side. This is, however, quite different from the typical convulsion with its tonic and clonic phases and loss of sensibility. Sommer [16] gives absolutely negative results with 23 offspring. Grainger-Stewart,[17] in observations covering considerable time, has never had a case of epilepsy in offspring of epileptic animals.

I. *Offspring of Epileptic Male and Normal Female.*

In this class 52 young were under observation, and in no case was there an animal presenting any abnormality, and there were only 4 deaths, making the mortality only 7%.

II. *Offspring of Normal Male and Epileptic Female.*

Of the 26 offspring in this class, only 15 were alive at birth and one died on the second day, leaving only 14 for study. Thus, there were 46% of deaths among the young of the epileptic female.

III. *Offspring of Epileptic Male and Epileptic Female.*

Of the entire 73 young in this division, 18 were dead at birth and 3 extremely weak ones died on the second or third day. These showed no paralysis. If stimulated by stroking the head or sides while lying on the back, there was free movement of all the limbs, but not sufficient strength to walk or eat. The mortality here was 29%. Comparing this with the above, it would appear that fewer offspring of the epileptic female survived than in the case of both epileptic parents. This is due to the fact that the injury was bilateral, and frequent convulsions were produced in all cases in Class II, while in the later cases, in Class III, the attacks were restricted and very few were produced, not more than one weekly, after being fully established. The change is clearly indicated by the fact that previous to the limitation of convulsions there were 54% of deaths, while following the restriction there was a mortality rate of only 21%. Aside from this there was no abnormality. No transmission of convulsions was found.

IV. *Offspring of Animals of the Second and Third Generation.*

Since no direct transmission occurred, the work was further carried on to find if alternate heredity according to the Mendelian principle would result here. Ten young of the third generation and 3 of the fourth failed to present anything notable.

IX. SUMMARY.

I. Lesions occurring in the cord or principal nerve trunks of guinea pigs produce a tendency to convulsions resembling epilepsy in the human subject. The attacks, however, have not been proven spontaneous, but may be elicited by irritation of a specific zone of skin on the side of the face and neck corresponding to the injured nerve. In this series 97% of the animals in which the sciatic nerve was resected developed convulsions; the remainder, 3%, showed only the scratch reflex.

II. The scratch reflex, the first manifestation of the nervous lesion, developed at the end of a period averaging eighteen days after the division of the nerve.

III. The complete convulsion appeared on an average of one month and nine days following the injury to the nerve and eighteen days after the development of the scratch reflex.

IV. Age proved not to be an absolute factor in relation to the time of development of the convulsions. Among 4 animals operated upon at the same time, varying from over eight months to one month of age, the youngest animal developed the convulsions first, only thirty-three days following injury. The age is ordinarily judged by weight. The average weight of a guinea pig at one month is slightly less than 250 gm.

V. The zone of irritation varies in extent. The sensitive area is at first limited to the skin over the side of the face. This extends progressively with the further development of the convulsive tendency to include the shoulder and often some distance beyond the border of the scapula. The degree of sensitiveness varies in individual cases. Sometimes merely touching the hair will produce an attack, while in others definite molding of the skin is required.

Trophic changes occur in the zone of irritation, manifested often by falling of the hair, leaving the skin exposed; or it may be the hair becomes brittle and breaks off, thus causing a roughening of the coat. In extreme cases the skin may ulcer-

ate. As a rule parasites accumulate over the area and there is some anesthesia.

VI. The convulsion follows irritation of the sensitive zone and is preceded by the scratch reflex. Following this, the animal falls on its back with eyes closed, insensible, and all its muscles in a state of tonic, followed by clonic, convulsion. The attack is usually brief, but may be spontaneously repeated several times. For some time following the return of consciousness the animal is somewhat stupid and dazed.

It was found that the animals would in most cases respond to repeated irritation, though some could be made to react only once without an interval of some hours to a day or more.

Severity of attacks depended on the size and physical condition mainly, though no rule could be applied to all cases. Those developing the attack most quickly were subject to the most severe convulsions.

VII. The effect of convulsions was productive of a marked loss of flesh, and this bore no relation to the quantity or quality of food given.

Lessened reproduction was also universal, and in almost every instance of birth of young they were not alive or died immediately after birth. This was proved not to be due directly to the division of the nerve, for by limiting attacks to not more than one each week, perfectly normal offspring were born. This would seem to show a marked disturbance in metabolism due to frequent convulsions.

VIII. The study of 128 offspring of epileptic animals to observe the transmission of epilepsy, reported by Brown-Séquard[5] to have been seen in his series, was absolutely negative. Four young were very weak at birth and died on the second day, but showed no other symptoms. The fact that *convulsions in the offspring of epileptic animals always, in Brown-Séquard's experience, existed with a lack of toes,** makes it seem possible that there may have been some pre-natal injury which would produce the same effect as a division of the nerve.

The 13 young of the second and third generations were also negative.

A microscopical study of the trunk organs from these animals should be of interest to compare with that of a series from the human subject.[18]

The nervous system of animals having had frequent convulsions, if examined histologically, might reveal something singificant, and the skin lesion existing in the zone of irritation has never received more than gross consideration. These lines, if followed out, would add much to the complete study of Brown-Séquard's epilepsy in guinea pig.

Clinical Department.

AN EXTRA-UTERINE PREGNANCY AT FULL TERM.*

BY C. H. HARE, M.D., BOSTON, MASS.

It was the writer's great pleasure to assist Dr. Swift in his operation upon a case of full-term extra-uterine pregnancy which he reported to this Society on Jan. 18, 1898, and which report was later printed in the Boston Medical and Surgical Journal, May 12, 1898. That case was operated forty-five days after the supposed death of the child. The placenta was removed. Most of the membranes not removed. The abdomen was closed without drainage. There was considerable shock, but otherwise the convalescence was excellent. The following summer a second case was seen in Paris. Pinard made the diagnosis of extra-uterine pregnancy at about five and one-half months. The patient was taken into the hospital and watched until a living child was removed from the abdomen by Ségond a short time before labor would have been expected had the pregnancy been intra-uterine. The placenta and membranes were not removed. The membranes were stitched to the abdominal incision and the sac drained. The writer first saw this case between seven and eight weeks after the operation, at which time both mother and baby were in the best of health. The abdominal sinus was then about the size of a child's little finger. My third case to see was operated by myself.

Mrs. C. C., 1451, was first seen March 30, 1910. Aged thirty-three years. Married ten years. One child, nine years of age. No abortions. Menstruation began at sixteen and had always been regular and normal. She has never had any pelvic trouble. The last and regular menstruation occurred May 6, 1909. There was no more flow until March 20 to 22, 1910, when she used some dozen napkins and passed a few clots after an ether examination. She had severe lower abdominal cramps on June 6, after which she was in bed for about six weeks with much nausea and vomiting and a large loss in weight. She was then fairly well

* Read at meeting of the Obstetrical Society of Boston, Oct. 25, 1910.

until cramps began about Christmas time and troubled her at times until Feb. 12. She felt life daily from October until Feb. 12, but never after that date. The abdomen steadily increased in size from October to February, and the leg and thigh veins became prominent. She had no question of her pregnancy and expected her confinement Feb. 10. On Feb. 12 from 9 A.M. to 4 P.M. she had mild labor-like pains which she hourly waited to have severe enough to send for her physician. Instead of which, however, they ceased. In the next few days the breasts became swollen and leaked. The abdomen and the large veins gradually lessened in size. When seen March 30 she weighed one hundred and thirty pounds, having lost ten pounds in six weeks. Her mental and nervous condition forbade a satisfactory examination. The cervix had practically disappeared, but there was a pencil-size hole high up and near the pubes on the left. A soft solid mass filled the pelvis and abdomen up to the navel. The ether examination had been made by two men of exceptionally large obstetrical experience, who found the uterus empty and the uterine canal three and three-fourths inches deep. They thought it most likely that she had a rapidly growing fibroid and that the pregnancy idea had been an error. My knowledge of the literature acquired through the case of Dr. Swift was fresh in memory, owing to the rarity of his case; hence, with the typical signs of a pregnancy over a period of nine months ending with a pseudo-labor and then the disappearance of pregnancy signs as the literature tells us to be typical of such cases, my first guess for diagnosis was an abdominal pregnancy at full term with death of the child on Feb. 12. She was operated April 6. A few ounces of dark serum were visible on opening the peritoneum. The fetal sac was ruptured and a dead baby weighing four and three-fourths pounds removed. The head was in the left pelvis. The placenta was fist size and shape in the right pelvis, easily removed, harder and stiffer than normal and weighed two pounds. The child and inside of the sac were very thickly covered with vernix caseosa and fine hairs. The uterus was soft, double normal size and lying in front of the sac. The sac was about the thickness of intestinal wall, but firmer and, barring the abdominal wall to which it had no adhesions, it was as if so firmly pressed into everything it touched that it was a part of and inseparable from everything touched. Only a small upper portion was removed. From the pelvic portion an opening was made into the vagina; a T-tube placed for drainage; and the cut edges of the sac infolded and sewed tight. Tubes, ovaries and appendix were not seen. There was no hemorrhage. More blood was lost from the vaginal puncture for the drainage tube than from any other source. The baby and placenta were given to Dr. Leary, who tells me they are simply like the usual dead and macerated specimens and nothing remarkable about them. The operation was well borne. The highest temperature was 101° and pulse 110 on the second day, after which it was never above 99° or pulse above 95. There was profuse discharge from the tube, with much odor, for several weeks. She left the hospital four weeks from the day of operation, but the drainage tube was not removed until twelve days later. Her convalescence was ideally good. The writer has seen her only once since operating, but by letter four days ago she tells me that she is completely tired out and in poor general condition owing to the care of an invalid mother since her return from the hospital, yet her menstruation is the same as before the operation and she has no pelvic pain or discomfort of any kind.

Diagnosis, care and operation on these cases is, of course, most vital. No man's personal experience, owing to the rarity of cases, can be sufficient to make him an expert, and as time goes on it is probable fewer cases of ectopic gestation will escape early diagnosis and early operation; hence any one individual's experience is likely to lessen. We are indebted to Sittner for exhaustive work upon extra-uterine pregnancy at term in papers published in 1901 and 1908. This writer collected reports of 165 cases of viable fetus at the time of operation from the year 1813 to 1906. Of these he could follow 122 sufficiently long to tell us that 63 lived beyond the first month, 23 beyond the first year, 6 beyond the sixth year, and one to the age of nineteen. His statistics on deformities report, of 93 children, 10 as badly deformed and 5 so badly as to cause death. A paper by Peterson, of Ann Arbor, in December last, reviews the papers of Sittner and a few others since published, and ends with the following conclusions.

First, wherever conditions permit, operation for the removal of the gestation sac is indicated in the first half of an extra-uterine pregnancy, since,

Second, at this period the mother is in great danger from rupture and sepsis; and,

Third, the chances for the survival of the fetus are very poor.

Fourth. During the latter part of an extra-uterine gestation the chances of rupture and a fatal hemorrhage are very much less (4.8%); and

Fifth, the chances of the survival of the fetus are very much greater.

Sixth. While malnutrition and malformation of the extra-uterine child are more common than with the fetus under normal conditions, they are not frequent enough to contra-indicate attempts at saving its life.

Seventh. Hence, under favorable surroundings, when the patient can be watched, she should be allowed to go within two or three weeks of term before operation.

Eighth. Since the maternal mortality is more than twice as great after operations in advanced extra-uterine pregnancy where the placenta is left behind,

Ninth, its removal should be one of the cardinal principles of each operation.

Tenth. In the "discoid" variety of placenta where only a small surface of this organ is not attached, the blood supply must be controlled, either by tying the vessels or by compression of the aorta before an attempt be made to remove the placenta.

Eleventh. When for any reason removal of the placenta is impossible, the sac should be stitched to the parietal peritoneum and the placenta shut off from the peritoneal cavity by gauze.

Twelfth. Dependent drainage through the vagina should be secured whenever possible.

THE profession in Russia celebrated, in various ways, Nov. 26, the hundredth anniversary of the birth of Nicolai Pirogoff, the great Russian surgeon, chief of the military medical service during the Crimean and the Russo-Turkish wars, and long professor of surgery at the Military Academy. His first work, published in 1836, on the anatomy of arteries and fascia, not only gave him an international reputation, but blazed the way for the surgery of the future. — *Jour. Am. Med. Asso.*

Medical Progress.

PROGRESS IN SURGERY.

Thoracic Surgery.

by samuel robinson, m.d.

At the Chicago meeting of the American Medical Association in 1908 a symposium on thoracic surgery was held and later reviewed in the columns of this Journal. [1]

Considerable interest prevailed in the discussions concerning the comparative value of the positive and negative pressure methods of avoiding the ill-effects of operative pneumothorax, and although clinical experience with the use of apparatus was then too small to be of value it was evident that the use of differential pressure might open a new era in thoracic surgery. Such hopes have been realized in a striking activity of experimental and clinical investigation which promises a lowered mortality from thoracic disease. The progress may be reviewed from the experimental and clinical aspects.

EXPERIMENTAL INVESTIGATION.

1. *Apparatus.* The old controversy between the advocates of plus and minus pressure is rapidly closing. The blood-pressure experiments of Seidel, Dreyer and Robinson have shown that positive differential pressure when properly administered does not disturb the physiology of respiration and circulation. The operations of Kuettner under negative and positive pressure have demonstrated the like practical applicability of the two. Innumerable operations upon animals and human beings under positive pressure have been sufficiently successful to warrant its continued use. The simpler and less expensive method then has naturally become the popular one and no fewer than fifty devices for the application of positive pressure have now been presented.

Conceiving the interesting idea that negative pressure may be better adapted to certain pathological conditions within the thorax, Willy Meyer has constructed a double cabinet for the combined use of plus and minus pressure with mechanism for prompt transition from one to the other.

Positive pressure cabinets large enough to contain the anesthetizer and the patient's head have been designed by Engelken, Meyer and Robinson, and are in use in Breslau, New York and Boston.

The head helmet with openings for the patient's head and the anesthetizer's hands continues to be the choice of Brauer and Janeway, and Karewski contributes another such apparatus with slight modifications. Mayer, Tiegel, Schmieden, Widal and Robinson remain satisfied that the purposes of differential pressure can be accomplished with the face mask method. Mollgaard and Flint have since constructed apparatus applicable to the mask method, with ingenious improvements in the control of the etherizing and exhaust segments.

Matas, Kuhn, Green, Dorrance, Fell, Richter and others have continued to advocate the use of peroral intubation, although it may be said that their methods more nearly approach the older custom of rhythmical artificial respiration than the principles of differential pressure, which presupposes the use of a constant, uninterrupted stream of air.

While the interest of investigators in the Sauerbruch differential pressure idea was at its height, Volhard and Sollmann were demonstrating that, in the presence of a wide open pneumothorax on both sides, oxygenation of the blood can be maintained without inflation of the lungs provided a constant stream of oxygen is introduced in the region of the bifurcation of the trachea. This, of course, involved either the introduction of a tube through a tracheotomy wound, or through the mouth, larynx and trachea. Robinson, in 1908, published the results of animal experiments in which he had verified the investigations of Volhard and Sollmann, and further added that while oxygenation could be maintained with intratracheal oxygen in the presence of almost complete lung collapse, it could not be maintained with air alone without at least a two-thirds inflation of the lung, even when the air supply was provided at the bifurcation of the trachea. Meltzer and Auer have explained these phenomena from a physiological standpoint and have perfected the method of introducing air through a tube to the bronchial bifurcation, calling the method "intratracheal insufflation." They have satisfactorily demonstrated that in a curarized animal, with the front of the chest removed, oxygenation is preserved with the lungs quiescent in a state of normal inflation. Inasmuch as the introduction of a tube in the dog is a comparatively simple procedure, many investigators have come to employ this method in their experimental intrathoracic operations. Elsberg has constructed an apparatus applicable to the human, and it is supposed by some that this intratracheal insufflation will eventually supplant the other methods.

Simplicity, portability, inexpensiveness, are features which recommend the insufflation method to its supporters. The advocates of the cabinet, mask and helmet methods argue that in thoracic operations on the human the avoidance of all intrabuccal and intratracheal instrumentation is of value, not only because of the difficulties attending intubation in certain individuals, but also because of the frequent intolerance of the pharynx and trachea to foreign bodies in spite of deep local and general anesthesia. It is doubted whether the introduction of a tube to the bifurcation of the trachea even in the most suitable patient is simple enough to warrant its practice after the opening of the thorax and the onset of symptoms which indicate the need of differential pressure. If we assume that at such a crisis an attempt at intubation might threaten the life of the patient, it would seem to be necessary to introduce a tracheal tube in all patients under-

[1] Progress in Surgery, James G. Mumford: Boston Med. and Surg. Jour., vol. clix, Nos. 23 and 24, pp. 760–763; 796–798.

going thoracic operations. Those who employ the other forms of apparatus, recognizing their ease of immediate application in case of need, and knowing, furthermore, that in a large percentage of thoracic operations no pressure is necessary, have come to operate with apparatus at hand, but without its application until necessary. Operators have remarked upon the consolation obtained from the immediate availability of means of differential pressure, although in the course of a doubtful operation it may not have been found essential. It has been argued further that all thoracic operations which may need artificial inflation are of a nature which demand hospital treatment, and that ease of portability beyond that of moving apparatus from one hospital to another is not a feature in support of the use of intratracheal insufflation unless the latter method can be shown to have more practical advantages. It has been mentioned, too, that thoracic operations of the type referred to are ordinarily of sufficient shock to the patient without the addition of intratracheal instrumentation. Again it is argued that in a large majority of thoracic operations but one cavity is opened, and that inasmuch as the remaining lung in the majority of cases continues to functionate enough to prevent a too great accumulation of carbon dioxide in the space between the lips and the bronchial bifurcation, the introduction of air as deep as the bifurcation is not essential, and that moderate pressure applied at the nose and mouth is sufficient to accomplish the desired result. Tiegel, recognizing the contribution of Volhard, has by the mask method substituted oxygen for air in his mask differential apparatus and becomes satisfied in a series of operations on the human that oxygen at a pressure of 1 cm. of water, although not enough to inflate the lung, is sufficient to maintain oxygenation. In cases of double pneumothorax, oxygen under greater pressure with resulting inflation may be necessary. He even recognizes that in many cases there is sufficient functional activity of the unoperated lung to inhale enough oxygen from the mask without resistance to its escape to preserve the normal heart action; he nevertheless advocates the use of pressure in conjunction with oxygen because of its necessity in double pneumothorax, in tracheal obstruction, in case of need of artificial respiration and for inflation of the lung before closure of the thoracotomy wound.

2. *Experimental thoracic operations.* Excision of greater or less portions of the lung tissue has continued to be a popular problem of experimental investigation. It is now universally admitted that excision of one or two lobes of the lung in dogs or rabbits is attended with absolute success, the manner of treating the lobe stump being of comparatively little importance and attended with like success with mass ligatures or with special treatment of the bronchial stump. (Tiegel, Green, Robinson, Danielsen.)

Total extirpation of one lung in animals has now come to be regarded as a procedure with low mortality. Sauerbruch and Robinson, who had performed total pneumectomies under negative and positive pressure respectively, had met with opposite results. They conclude that the explanation of success with negative pressure rests in the fact that at the close of an operation in a negative pressure cabinet the persisting pressure in the emptied side of the thorax is equal to that of the unopened side and that the conditions are favorable, therefore, for the compensatory hypertrophy of the remaining lung and for the displacement of the heart and lung to occupy the hollow pleural cavity. In a long series of animal operations under positive pressure, in which no effort was made at the end of the operation to reexpand the remaining lung or otherwise to obliterate the atmospheric pressure of the open side, the mortality was high. They, therefore, recommended the necessity of hyperinflation of the remaining lung at the close of operations for total pneumectomy in dogs. Flint has since proved the importance of this suggestion. After pneumectomy he sutures the thoracotomy wound, leaving a bent glass tube, which, under hyperinflation of the remaining lung, is suddenly removed as the last mattress suture is tied. He has also produced an absolute negative pressure within the empty thorax by post-operatively aspirating the hollow thorax until by manometer reading the normal negative pressure was produced. By these two methods he has performed seven total pneumectomies with two deaths. Von Eberts has likewise been successful with the aspiration method. It is of interest that in Flint's operations the inversion of the bronchus with peribronchial stitch, recommended and successfully employed by Meyer, was not considered essential, and it is further noticeable that the successful total pneumectomies under negative pressure performed by Sauerbruch were done with mass ligatures of the stump and vessels. From these factors it may be concluded that bronchial leakage is less likely to occur if the normal negative pressure is preserved after pneumectomy, and that the previous fatalities have been due more perhaps to neglect of this feature than to lack of care in the closure of the bronchus. The most successful series of total pneumectomies in dogs is that of Willy Meyer, with seventeen successes in twenty-one operations. The fact that negative pressure was employed in most of these operations, together with particular care in closure of the bronchus, leaves us undetermined as to which was more responsible for his results.

The technic of closing wounds in the lung has been presented in several forms by Talke, Green, Mayer, Dorrance, Tiegel and others, and the like success of the varying methods has led us to conclude that suturing of cuts, lacerations, and other wounds of the lung tissue is a simple and successful procedure. Dorrance reports a series of eighteen experiments in which stab wounds were inflicted, stating that hemothorax was present in a large proportion of cases and that operation and suture under such conditions were successful in thirteen animals.

The esophagus has also been the seat of active

experimental investigation, and it may be said that all such experiments have been made possible by the introduction of differential pressure, the use of which is absolutely essential in esophageal operations upon the normal dog. Tiegel, Sauerbruch, Green and Janeway, Meyer and Mayer have done progressive work along these lines, although results are somewhat discouraging. Thus far efforts to approximate the proximal end of the esophagus and stomach after resection of any considerable portion of the esophagus have been attended with a high mortality. The use of buttons for such anastomoses has been to a great extent abandoned on behalf of the direct suture, but leakage has occurred even with the latter, partly, if not wholly, as a result of the excessive tension on the approximated parts. Green and Janeway have found that the approximation of the proximal portion of the esophagus and the prepyloric portion of the stomach is possible, and they report a series of six favorable results after excision of the lower esophagus and cardiac portion of the stomach.

Experimental surgery of the heart has contributed features which will undoubtedly be of value in operations on the human being. Haecker and Sauerbruch have demonstrated the practicability of the transpleural approach to the heart. They claim that this approach is of value primarily because many bullet and stab wounds of the heart involve the pleura and lung, and that heart suture without the repair of lung injury and the removal of hemo- and pneumothorax is an incomplete procedure. They have demonstrated that, with the pleura opened under low differential pressure, the concurrent slowing of the pulse-rate facilitates suture of the heart muscle. They advocate, furthermore, temporary pressure of the vessels at the base of the heart during the introduction of sutures to the ventricles to diminish the blood leakage after the opening of the pericardium, and they have shown that almost complete occlusion of these vessels may be maintained in rabbits for more than a minute without fatal results.

The introduction of differential pressure has made possible certain investigations in pathological physiology in which valvular lesions have been artificially produced by the introduction of ligatures in the region of the mitral valve. Carrel has removed and transplanted sections of the thoracic aorta and vena cava.

I. THE NASAL PHENOMENA OF NEURASTHENIA.

By Charles Prevost Grayson, M.D. (Abstract.)

Frequency and severity of neurovascular nasal disorder as a complication of neurasthenia. Of too common occurrence to be regarded as merely coincidental. Possessed of therapeutic as well as pathologic importance. Occurs in both essential and symptomatic neurasthenia, and in both the nasal phenomena are unmistakably of nervous origin. Not to be confused with hay fever or vernal catarrh. No hypersensibility to irritants of external origin. Disturbing factor evidently comes from within, and its action is probably central rather than peripheral. Although ordinary symptoms of peripheral irritation may be absent, yet the actual intranasal conditions are as strongly marked in neurasthenia as in the periodic violence of hay fever. Vaso-paresis and infiltrative tumefaction of turbinates pronounced. Quite sufficient to account for or, at least, aggravate the headache, mental apathy and even the melancholia of neurasthenia. Its relief, therefore, of considerable therapeutic importance with reference to cure of the central nervous derangement. It is an example of the danger of prolonged alteration of physiologic processes eventuating in actual pathologic changes. The repeated disturbance of arteriovenous balance in nasal mucosa leads in time to persistent vasoparesis with all its consequences. Therapeutic neglect of this condition will greatly hinder the success of general treatment of the neurasthenia. Local measures of relief: Cauterization alone of little value, but if serum-distended turbinates are first drained by free scarification or multiple puncture, chromic acid or galvano-cautery will then prove effective. Glycerophosphates and strychnine of collateral systemic value. Analogy between results of local treatment in these cases and the removal of adenoid growths in children. Mental improvement equally prompt and remarkable.

Dr. B. R. Shurley, Detroit, said that there are a number of cases that come under the observation of the rhinologists which are classified under the term of neurasthenia, and they are perhaps the most abused of all that come under the observation of the different specialists. He had been greatly interested in some problems along this line, and some time ago had been privileged to make observations on carrier pigeons after a long flight, — making sections of the spinal cord and observing the action of fatigue under the microscope, — and there is a complete change in the cell structure of the pigeon that has been over-fatigued as compared with one that has been at rest. He is confident that in all these cases there is a definite reason, which we are not always able to ascertain, to explain the different vasomotor neuroses so often presented. Another class of cases has been demonstrated to be due to actual changes in the natural secretions. This is in the line of physiology, and we are just beginning to understand that a large number of these so-called neurasthenics are cases of atypical Graves' disease and myxedema. Dr. Grayson had spoken of the effect of the glycerophosphates on the throat, and the marked changes in the air passages. There is a drying of the air passages in some of these neurasthenics which responds promptly to properly regulated doses of sheep's thyroids; iodine, also, is of great value in regulating this condition. Many of these thyroid conditions are due to loss of balance of the governing influence of the thyroids, pituitary bodies, etc., and by supplying the deficiency in the body when indicated results are reached that are well worth while.

Dr. Solis Cohen, Philadelphia, remarked that Dr. Sajous, who is at present in the lead in the investigations of the internal secretions, had stated that he owed his interest in the subject to the attention paid to thyroid cases when he was in Dr. Cohen's clinic.

DR. J. P. CLARK, Boston, said that while there may be cases in which the nasal symptoms are due to what is termed neurasthenia, yet none would feel satisfied in making a diagnosis of neurasthenia for nasal conditions, and if some physical conditions, such as described by Dr. Grayson, could be found, we would all be pleased. The more we know of nasal conditions, the more cases we will be able to remove from the classification of neurasthenia. In one case he had treated both antra contained a thick glairy mucosa which came out in almost a solid mass, and by clearing out the antra the patient was entirely rid of the local symptoms that were affecting his health very markedly. That belonged to the class of cases that might easily have been overlooked and classified under neurasthenia.

DR. R. C. MYLES, New York, said that he had found in cases of neurasthenia the same nasal phenomena described by Dr. Grayson. The conditions have sometimes a common and sometimes a local cause, and the difficulty seems to be in differentiating at the outset the proper relief for these cases. They do not stand manipulative procedure well, and certain types have to be referred back to the general physician to be relieved of their toxemic conditions. It is a peculiar fact that during the past winter he has seen more incipient thyroid cases than in the ten years previous. Whether or not this may be due to the extensive use of thyroid extract, he could not say.

DR. H. L. SWAIN, New Haven, said that in considering this matter we should bear in mind that there are anatomical conditions and physical deviations in the mucous membranes of those who suffer from rhinitis or disturbed internal secretions differing from those possessed by persons with normal structures. His work in cases of edematous rhinitis has convinced him that these patients have thinner vessel walls, less fibrous connective tissue distributed through the membranes and fewer of the muscle elements which contract than in other pathological conditions; and in this lack of firmness in the texture of the vessel wall there is the physical cause for the condition in the nose. He agreed with Dr. Shurley that there are types of exophthalmic goiter or myxedema which are responsible for many of the phenomena in these cases of nerve tire or neurasthenia.

DR. GRAYSON said that he would not for a moment presume to make a diagnosis of neurasthenia simply from the nasal conditions, but that a large proportion of such cases manifest the phenomena he had described. In the cases described the conditions persisted for months, many with scarcely any remission, and must have been due to other conditions than autotoxemias, for under treatment their general condition had greatly improved, yet the local condition continued. Dr. Shurley's remarks about the pathological conditions were decidedly illuminating, and when further studied may prove of decided benefit to this class of patients.

II. A COMPARATIVE STUDY IN THE ANATOMY OF MAN AND THE ANTHROPOID APES, WITH THEIR PHYSIOLOGICAL SIGNIFICANCE; EXHIBITION OF GROSS AND MICROSCOPIC SPECIMENS.

DR. T. GORDON WILSON, Chicago.

Dr. Wilson pointed out that the evolution of the larynx from a sphincter-like organ at the entrance to the respiratory tract to one in which the primitive function was overshadowed by the part now played by it in inter-relational life made the larynx especially interesting and important for comparative study. The paper was confined to a study of the ventricles and their appendages, and to the relation of the thyro-arytenoid muscle to the inferior vocal cord. Gross and microscopic examinations have been made of the larynges of a white man, a Chinaman, an orang-utan, several macacus monkeys, and a marmoset. By means of lantern slides and microscopic sections thrown on the screen the various points in the progressive series were demonstrated, especially the approximations of the muscle to the inferior vocal cord. In the second part of the paper there were discussed the various hypotheses which from time to time have been advanced to account for the presence of ventricles in the larynx. It was held that however adequate some of these hypotheses might appear to be to explain the presence of ventricles in one species, the impossibility of applying any one hypothesis to the anthropoidea in general was an obvious defect. Dr. Wilson insisted that if any general function was to be associated with the laryngeal diverticula, one must look for it along the lines of the general principle underlying laryngeal development, namely, the requirements of inter-relational life. With this in view, it was suggested that by means of such sacs the animal was able to modify the voice to express emotional states. In man, the close approximation of the musculature to the cord offered a finer mechanism to produce the same result, and so one would expect a diminution in the development of the diverticula. This appears to be so.

DR. J. PRICE-BROWN, Toronto, told of the case of a young woman twenty-five years of age, with a tumor in the neck which was soft and would disappear on inspiration and appear on expiration. He had concluded that it was a laryngeal sac, although he had had no previous knowledge on that subject, and that it was filled by air. His confrères had disagreed, and thought it was a thymus or thyroid gland and was drawn into the thorax during inspiration. He wished to know Dr. Wilson's opinion on the subject.

DR. WILSON replied that the question of laryngeal sacs was a very complex one, but that he had little doubt the case described by Dr. Price-Brown was a laryngeal sac. A similar case is reported in literature.

III. EXHIBITION OF ANATOMICAL PREPARATIONS DEMONSTRATING COMMUNICATIONS BETWEEN THE BLOOD VESSELS SUPPLYING THE DURA, THE ORBIT AND THE NASAL CAVITIES.

By DR. GEORGE E. SHAMBAUGH, Chicago.

Zuckerkandl, by injecting the longitudinal sinus, has been able to inject the mucosa of the frontal sinus and some of the mucosa of the nasal cavities, and recently Killian has demonstrated the blood-vessel communications between the frontal sinus and the dura, but further than this little important work has been done along these lines. The question seems one of great clinical importance, and Dr. Shambaugh undertook to demonstrate these communications on the heads of fetuses. Securing them quite fresh, he was able to do this very successfully. The heads were then decalcified and sections were removed, showing the nasal cavities, the orbit and the brain cavity. Thick sections were cut, colored and mounted on slides, and one can see in these the blood vessels going through. With a stereoscopic microscope there is no difficulty in demonstratng these vessel communications between the various nasal cavities and the dura. The anatomical preparations showed these communications very beautifully.

DR. H. P. MOSHER, Boston, said that every one must thank Dr. Shambaugh for presenting these beautiful specimens and bringing this subject up to date.

IV. THE MANIFESTATIONS OF RECURRENT INFLUENZA ON THE NOSE AND THROAT.

By Dr. Joseph L. Goodale, Boston.

Dr. James L. Newcomb, New York, said that he himself belonged to the class of cases described by Dr. Goodale, and that he wished to testify to the excellence of Deland, Fla., for such conditions. The air is dry and pleasant, and, furthermore, there is a good hotel there, which is not found in many Florida places, where you can lead a quiet life.

Dr. Casselberry said that the essayist had described cases symptomatically which are familiar to all, but that he himself has not been accustomed to ascribing them all to a common etiological factor, — there are other elements, and he wished to emphasize the good that will result in many cases of persistent tickling and irritation of the pharynx by the destruction of some one particular follicle or group of follicles in the pharynx. Of course the general cauterization of follicles in cases of follicular pharyngitis was familiar to all, but that was not the topic under discussion. The thorough cleansing of the secretions is next in importance as a therapeutic measure. His own experience in regard to abbreviating the course of these conditions differs from that of Dr. Goodale. He has frequently been impressed with the fact that after having endured for days they are cut short decidedly. He has had greater benefit from the dry climate of the West than from other localities.

Dr. H. L. Swain, New Haven, said that the patient will often assure you that you have hit the spot when you hit the lingual tonsil.

Dr. James E. Logan, Kansas City, said that the paper was very interesting to him in the light of some investigations he has been pursuing for a number of years. His experience has led him to believe that the infectious area is not to be attributed to the conditions in the faucial tonsils; they are more in the avenue of the digestive tract and are less liable to affect the upper respiratory tract than is usually believed. He is inclined to believe that the infections that pervade the upper respiratory tract are, to a large extent, located in the vault of the pharynx — you will find there the pneumococcus catarrhalis, the staphylococcus, the streptococcus, etc., in their various manifestations, but in so slight a manifestation that the little areas are easily overlooked. During the later years he has been able to find these recurrent "upholstered" conditions, which formerly he was not able to recognize as being of any value whatever, and he was glad to hear Dr. Grayson say that the pharyngeal tract is the place to look for these bacterial invasions. In his opinion, the only way to treat these conditions and prevent their recurrence is by the removal of these "upholstered" masses. He has found the application of a 30% solution of nitrate of silver to these recessi, through the oro-pharynx, very effective.

Dr. Joseph L. Goodale, Boston, said that he prefers the carbolic acid as the caustic agent during the acute inflammatory stage rather than the silver nitrate, which is best suited for use in the interval, to prevent recurrence. It requires a good deal of skill and practice to be able to treat the nasopharynx successfully.

V. QUININÆ AND UREA HYDROCHLORATE AS A LOCAL ANESTHETIC.[1]

By E. Fletcher Ingals, M. D., Chicago. (Abstract.)

Papers on this subject have appeared in the *Journal of the American Medical Association*, by Dr. Thiebault, 1907; Dr. E. J. Brown, 1908, and Drs. Hertzler, Brewster and Rogers, in 1909. The author of the present paper confirms the former statements that this is a safe and efficient local anesthetic, but he has not been able to demonstrate the prolonged action claimed by some of the other observers. He has used this anesthetic in many cases of nasal surgery, and in every instance has obtained excellent results. This drug in a 20% solution applied locally produces anesthesia as profound as a similar solution of cocaine, but it requires about four times as long to obtain results. A solution of 5% of cocaine and 15% of urea quinine in 1: 2000 of suprarenalin has been found most satisfactory. It acts as promptly and sometimes apparently more quickly than a 20% solution of cocaine in the suprarenalin solution. The reaction following cauterizations in the nares has been much less when this solution has been employed as an anesthetic than when the 20% solution of cocaine has been used.

Submucous injections of this drug have given profound and deeper anesthesia than its topical applications, but some of them have been followed by prolonged pain and a good deal of swelling. On account of the prolonged anesthesia claimed for this remedy, it would appear to be strongly indicated in the treatment of hyperesthetic rhinitis and hay fever. The author's experience does not make him as hopeful of the results in these affections as would have been anticipated from the former reports on the drug, nevertheless he considers that it should be given a fair trial. As a local anesthetic when used hypodermically in from ¼ to ½% solution, it appears to be very efficient, and it is shown to be absolutely safe by the fact that 100 gr. of the drug were injected into the veins by Brewster in the course of six hours in a case of pernicious malaria with recovery of patient. The author highly recommends this anesthetic in combination with cocaine and suprarenalin for all intranasal surgical operations.

Dr. Solis Cohen, Philadelphia, said that he has used this preparation for many years in general practice in remittent fever, especially pernicious fever. There is a form in which the patient suffers from chills, and if this is given in doses of 60 gr. it will often prevent paroxysms. He has used it also in removing growths from the larynx, with as much facility as with cocaine. He considers it a very satisfactory anesthetic.

Dr. Casselberry, Chicago, inquired whether Dr. Ingals had had any experience with it in tuberculosis of the larnyx. His remarks would seem to establish its utility in such conditions on account of its long duration.

Dr. Shurley said that he had started using this combination some time ago on the advice of a rectal specialist who had some most remarkable results with the infiltration of this anesthetic, but after using it on a few cases and hearing some unfavorable reports from others who had tried it, he discontinued its use.

Dr. T. Gordon Wilson, Chicago, said that he would like to know more about this from a different point of view. Some years ago he had been interested in the subject of the nerve endings, and the first thing that had to be done was to differentiate between the question of anesthesia and the question of nerve death: on the one hand, the suppression of the nerve function, and on the other hand, their death — protoplasmic death. The reason why you get so long an anesthesia is that you produce death of the particular nerve endings. It would, therefore, seem to be very dangerous to inject it into a nerve trunk.

Dr. John R. Winslow, Baltimore, said that for the past few months he has performed practically all his tonsillectomies under quinine anesthesia, with much

[1] Presented at the American Laryngological Association at Washington, May, 1910.

satisfaction, though in a stronger solution than usually used, — from 3 to 5%. By making the injection from fifteen to twenty minutes before operation, he finds that not only is the anesthetic effect increased, but that no hemorrhage follows the incision. He has had no bad results, though there is considerable swelling and edema for a while. His patients, however, do not admit that they are relieved of the after-pain characteristic of operations on the tonsils.

DR. H. L. SWAIN, New Haven, said that if the remarks made by Dr. Wilson in regard to protoplasmic death prove to be true, it would be very satisfactory. If the nerves in a tubercular lesion would remain dead until the patient passed away, we would have a great addition to our armamentarium.

DR. SOLIS COHEN said that he had had under treatment a very severe case of tubercular ulcer of the larynx in which this anesthetic allowed the patient to swallow for two or three days. A 20% solution was used. It required two or three minutes to produce the anesthesia.

DR. INGALS, closing the discussion, said that Dr. Cohen had answered Dr. Casselberry's question. He himself, however, had found that it required from fifteen to twenty minutes to produce the anesthesia. As to the discomfort arising from the injection, he judged that there was a good deal of swelling and that the patient might be very uncomfortable. He had not injected the tonsil at all. He and Dr. Wilson had discussed the subject of the nerve endings a few days earlier, and had agreed that it would be a fine thing if the nerve endings could be killed for a time at least. His experience in regard to eliminating the use of a vasomotor constrictor has been different from that reported by Dr. Winslow — the bleeding seemed to be as great as after any other anesthesia. According to his understanding, there is considerable anesthesia, lasting perhaps for ten or twelve hours.

VI. THE SYNDROME OF THE SPHENOPALATINE GANGLION.

By DR. GREENFIELD SLUDER.

DR. HARRIS P. MOSHER, Boston, said that asthma can in quite a number of cases be stopped promptly and for a moderate length of time by proper treatment directed to the sphenopalatine ganglion, and that we are indebted to Dr. Sluder for the first definite and full anatomical description of this ganglion. He has also successfully treated an obstinate case of moderate rhinitis.

DR. T. GORDON WILSON, Chicago, said that to him the most interesting part of the paper was the association of definite nasal symptoms with lesions affecting a sympathetic ganglion. The changes in vasomotor and secretory disturbances described by Dr. Sluder are important and suggestive, but the gustatory phenomena which he finds are difficult to reconcile with our present accepted knowledge of the course of these phenomena. The results of testing for taste in the anterior part of the tongue are subject to so much variation in healthy individuals, are subject to so much variation, that most men who have worked on this subject agree that to obtain reliable results taste must have been carefully tested before as well as after operation. The absence of such a record appears to lessen the value of Dr. Sluder's findings.

DR. SLUDER, closing the discussion, said that Dr. Mosher's observations on asthma were most interesting, and he hoped to try it in such cases. He was familiar with the work of Dr. Stein, of Chicago, who proposed treating cases of sneezing vasomotor rhinitis by injection into the nerve trunks as they enter through the sphenopalatine foramen. His own attempts with this condition have been few, and the results have been disappointing. He had been careful in expressing himself in regard to dealing with the question of taste. There is no anatomy, so far as he knows, to explain these phenomena — they are apparently inexplicable. He is also aware of the difficulty of dealing with the subject of taste in the anterior two thirds of the tongue. He has tried to follow the literature of the sense of taste, but it is exceedingly extensive, and he has no idea that he has read it all.

(To be continued.)

Book Reviews.

A Textbook of Veterinary Anatomy. By SEPTIMUS SISSON, S.B., V.S., Professor of Comparative Anatomy, Ohio State University, College of Veterinary Medicine. Octavo of 826 pages, 588 illustrations. Philadelphia and London: W. B. Saunders Company. 1910.

This fine piece of bookmaking containing 826 pages, including the index, is comparable to the best works on human anatomy, and is a decided addition to good veterinary literature of English-speaking people.

"The lack of a modern and well-illustrated book on the structure of the principal domestic animals has been acutely felt for a long time by teachers, students and practitioners of veterinary medicine," says the author in his preface, though he might have added "in English," for foreign languages offer excellent comparative anatomies, for example, Ellenberger and Baum "Handbuch der Vergleichenden Anatomie der Hausthiere." Yet it is not amiss to say at once that the work under consideration ranks with the best.

Modern methods of preparation have materially altered prevailing opinion regarding the normal form of certain of the viscera, and the results are given in this volume. "Embryological and histological data have been almost entirely excluded, since it was desired to offer a textbook of convenient size for the student and a work of ready reference for the practitioner."

"Veterinary anatomical nomenclature is at present quite chaotic in English-speaking countries," and so the author has endeavored to exclude certain terms which seem to fulfil no "useful purpose, and others which are clearly erroneous, or otherwise undesirable," and "in many cases the terms agreed upon by the Congresses at Baden and Stuttgart are adopted either in the original Latin or in anglicized form," an excellent plan.

Of the five hundred and eighty-eight exemplary illustrations, often colored, many are original and many are reproductions from Ellenberger and Baum, Leisering, Schmaltz and others, and it is pleasing to note that in all such instances proper acknowledgment has been made.

It is a distinct pleasure to review so admirable a work, a marked advance in English veterinary literature, upon which student and practitioner may well congratulate themselves and no medical school can afford to be without. It is an exhaustive gross anatomy of the horse, ox, pig and dog,

including the splanchnology of the sheep. There is but one regret, namely, that so extensive a volume should not consider the anatomy of the bird, taking the domestic fowl as the type.

An Introduction to the Study of Hypnotism, Experimental and Therapeutic. By H. E. WINGFIELD, M.A., M.D., B.C. Cantab. New York: William Wood & Co. 1910.

Hypnotism is a subject which too many physicians are prone to regard with suspicion, skepticism or contempt, and which sometimes suggests to them, as generally to the laity, ideas of the supernatural, the transcendental or the uncanny. Dr. Wingfield's volume presents it in its true light as the science of a psychic condition, dependent on definite psychologic and physiologic laws, and capable of being used for certain therapeutic purposes. After a sane and lucid exposition of the nature and phenomena of hypnosis and the methods of its induction, he describes the principles of legitimate treatment by suggestion and presents a rebuttal in refutation of the case against hypnotism. He makes frequent reference to the work of Sidis in Boston on this subject. Whatever one's prejudices, one cannot help recognizing and being impressed by his serious and absolute honesty of purpose and expression. His admirable book should be read with thoughtful attention by physicians as an introduction to the facts of a field in medicine of whose possible value and importance we are often ignorant or intolerant.

The Medical Record Visiting List, or Physicians' Diary for 1911. New revised edition. New York: William Wood & Co. 1910.

This convenient pocket diary not only provides space sufficient for a visiting list of sixty patients a week, but contains tables of valuable information which should be useful to the busy practitioner.

Hay Fever and Paroxysmal Sneezing (Vasomotor Rhinitis). By EUGENE S. YONGE, M.D. (Edin.), Physician to the Manchester Hospital for Consumption and Diseases of the Throat. Edinburgh and London: William Green & Sons. 1910.

This small book of one hundred and fifty pages is a valuable addition to the literature of this most perplexing disease, not that it contains much that is new, but because it is an able monograph on the subject by an able author. It is a brief compilation of the numerous speculations on etiology and the various methods of treatment, including the author's, of vasomotor rhinitis, so called. As a review it is complete, yet well edited and brief. His own conclusions are not always easy to find, being often blended with those of his predecessors. In general they are interesting and judicial, although not always convincing. He tries to draw a sharp line between hay fever proper, meaning those cases in which the pollen of different plants are evidently the exciting agent, and all other allied cases, grouping the latter under the title of paroxysmal sneezing or vasomotor rhinitis. By his own showing there is too much in common between these two groups to make this altogether logical.

For the last three quarters of a century the group of disturbances which includes the different hay fevers has been one of the most elusive of diseases; both its etiology and its treatment appear periodically to be approaching solution without ever getting there. Some victims sneeze only in June, others only in September; some cannot come near certain animals, others are affected only by something else. Asthma may or may not be related to it. Some cases are relieved or even cured by almost anything, yet others by something else or nothing. This is, therefore, a difficult subject to handle, but one which offers wide fields for etiological imagination. The author follows the lead of the majority of writers in looking at the symptom-complex as primarily caused by a weakness of the nervous system. Although giving credence to most of Dunbar's work, he does not quite arrive at the logical conclusion from this that lack of immunity to the different irritants may be due to the lack of a chemical neutralizing agent in the nasal secretions and that the nervous symptoms may be entirely secondary. He reviews the whole list of local operations which have been recommended, and adds one of his own which has given him good results. It consists in removing under general anesthesia the so-called tubercles of the septum, situated at the junction of the septal cartilage and the ethmoid plate. On the much-discussed question of the influence of intra-nasal deviations in producing the disease, and the benefit to the patient in removing them, he occupies a conservative middle ground. The pallor of the nasal mucous membrane which is often, in this country at least, a very characteristic feature of the disturbance, has not particularly impressed him. Although the disease as seen in England varies somewhat from that with which we are familiar in America, on account of the somewhat different exciting irritants, the careful study by the author of American authorities relieves the book of the objection of being foreign.

Education in Sexual Physiology and Hygiene. A Physician's Message. By PHILIP ZENNER, M.D. Cincinnati: The Robert Clarke Company. 1910.

The problem of teaching and learning the physiology and hygiene of the reproductive function is the subtlest and most difficult in the education of adolescents; indeed, it is one which many adults never solve for themselves, which humanity collectively has never solved. All efforts at its solution are tentative; many do more harm than good. The present volume represents the author's attempt, which has the merit of being serious and entirely right-minded. For young children his method seems well adapted. For older children, especially boys, it should seem that a shrewder tone of frankness were more effective. "Sexual virtue is the best policy" is the form which such instruction would have taken from the tongue of wise Ben Franklin.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, DECEMBER 8, 1910

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

REPORT OF THE MASSACHUSETTS TUBERCULOSIS COMMISSION.

IN the issue of the JOURNAL for March 17, 1910, we described and commented editorially on a resolve, then pending before the Massachusetts Legislature, providing for the appointment of a "commission to investigate and report upon a system of caring for tubercular patients by state and local authorities"; and in our issue for May 12, 1910, we announced the passage of this resolve, and the names of the commissioners as appointed by Governor Draper. This commission has prosecuted its labors during the past summer, and its report is now at hand. Embodying as it does the investigations and opinions of experts whose recommendations are likely to be of considerable weight, this report deserves attention and careful consideration Its principal data and conclusions may be summarized as follows:

There are estimated to be in Massachusetts approximately 35,000 cases of tuberculosis, of which probably 27,000 are pulmonary. For the accommodation of these cases there are, besides private hospitals, four state sanatoria, seven municipal tuberculosis hospitals, and ward or almshouse provision for tuberculous patients in 21 cities and towns. The hospitals and sanatoria, public and private, have 2,773 beds, accommodating rather more than 5,000 persons each year. The state institutions receive principally cases capable of arrest or cure; advanced cases are generally sent to municipal hospitals or to their homes.

Though recognizing the importance of caring for early cases, the commission considers the segregation of advanced cases to be the most efficient single measure in the effort to stamp out tuberculosis. It therefore recommends that the total accommodation for tuberculous patients be increased to 5,000 or 6,000 beds, chiefly in local hospitals. To encourage the establishment of these institutions, it recommends that the state pay a "subsidy of $5 per week for each non-paying patient in a local hospital which meets with the approval of the trustees of hospitals for consumptives, provided tubercle bacilli are demonstrated.' This sum is about half the weekly cost of maintenance of a patient in a tuberculosis institution, and the commission also recommends that the charge to paying patients at the state sanatoria be raised to the same amount. It makes further minor suggestions relative to the administration of these sanatoria; it advises the erection, in connection with the hospital school at Canton, of a state hospital school for tuberculous children; and finally recommends "that the legislature require the establishment of dispensaries for the discovery, supervision and treatment of cases of tuberculosis by the agency of the local boards of health, in all cities and towns with over 10,000 inhabitants." Four members of the commission believe it advisable, under certain restrictions, for local boards of health to supply needy tuberculous patients with food at their homes. The remainder submit a dissenting minority opinion of three that such relief should be given by private relief societies or overseers of the poor on recommendation from boards of health.

The most significant aspects of this report may be included under three topics, — state subsidy, tuberculosis dispensaries and food distribution. In regard to the importance of segregating advanced cases, the attitude of the commission seems sound. The advanced case, particularly if ignorant or unruly, constitutes the greatest menace to the community, because from him may be distributed the greatest amount of infecting material. The way to stop tuberculosis is to stop the infection of new cases. Supervision and control of advanced cases is, therefore, essential, and the commission believes this may best be obtained in local hospitals. The difficulty in the way of this, as of the attainment of all desirable things, is the expense. A state subsidy, whereby the commonwealth would halve with each community the cost of maintaining in segregation its non-paying tuberculous patients, would help municipalities meet this expense and probably hasten the erection of the needed institutions. Upon careful consideration, the commission believes that such subsidy would be a wise economic measure and would more than pay for itself in the saving of life and health by the decreased

incidence of tuberculosis resultant from more thorough segregation of advanced cases which in their homes are foci of fresh infection. Perhaps these sanguine expectations are justified. They certainly concur with the results attained by segregation in other infectious diseases. Before they become the basis of action, however, they should be subjected to rigid criticism, for in undertaking subsidy, the state is employing a dangerous agent. The taxpayer is already overburdened, and once the principle of subsidization becomes established and familiar, it is difficult to foresee to what extent it might be carried by those whose charitable enthusiasm is greater than their judgment or their own financial assets.

Similar comment may be made on the suggestions for tuberculosis dispensaries and the supplying of food. There is no end to the desirable things that communities might have, were there money enough to pay for them. But communities, like individuals, must count the cost. If they do not, their fate is the same. Doubtless tuberculosis is a great public evil, which is worth fighting, but so are venereal diseases, and so is cancer. Provisions for dealing with all these must be made gradually, with due regard for the capacities of the public purse. Moreover, the supplying of food is a measure which, though doubtless in certain cases desirable and humane, is, nevertheless, capable of dangerous, proletariat-building possibilities.

These comments are made not in opposition to the spirit of the report, which is a document of great value and importance, but merely by way of suggesting that there are two sides to some of the propositions which it advances. The principles upon which it lays out the campaign against tuberculosis are eminently sound. Only, in endeavoring to carry that campaign into effect, it should be remembered, with due consideration for the recommendation of experts, that human progress is necessarily slow, that something must be left to natural processes which can be aided but not hastened, and that in initiating any new measure of expense the project should be weighed as a question of policy as well as of theoretic desirability.

NOTIFICATION OF SYPHILIS AND GONORRHEA.

The California State Board of Health is the first to place syphilis and gonorrhea on the list of reportable diseases. This action was taken in a regulation recently issued, which reads as follows:

"*Be it resolved*, That the California State Board of Health declares that, beginning Jan. 1, 1911, syphilis and gonococcus infections shall be reportable and shall be placed on the list of communicable diseases which local boards of health and health officers are required to report to the secretary, it being provided, however, that until further action by this board, physicians may report the facts concerning these diseases by office numbers instead of names of patients.

"*Be it further resolved*, That this board officially calls the attention of the citizens of California to the contagious and infectious nature of these diseases and requests their co-operation in combating them by every available means — educational, sanitary, medical, social and moral."

The California State Board of Health shows much courage by taking the lead in applying to venereal diseases the same measures that experience has suggested for dealing with other infections. The first step towards control and suppression of any disease is a knowledge of the number and location of existent cases. For this the system of notification by number, if conscientiously carried out by physicians, makes a workable provision and should prepare the way for intelligent and concerted action, by education and prophylaxis, towards the eradication of diseases which are a far greater menace to mankind and to civilization than tuberculosis. It will be of interest to observe how this advanced example of California works, how soon it is followed by boards of health in other states and to what extent the position of the California Board will be carried out in practice.

TYPHOID FEVER EPIDEMICS.

Several minor epidemics of typhoid fever are in progress in various parts of the country. At Annapolis, Md., four more new cases developed during the week ending Dec. 3, making a total of twenty-four, as yet without fatalities, among students at the United States Naval Academy. At Lexington, Va., so many cases have appeared that Washington and Lee University was closed on Nov. 27, to stand closed until Jan. 3, 1911. This epidemic is supposed to be due to an infected water supply. At Windsor Locks, Conn., over fifty cases of typhoid have occurred since Oct. 15, and there have been two deaths. Poor sewage provisions are thought to be responsible for this epidemic. At Hyde Park there has been an unusually large number of typhoid cases this fall. The town board of health, suspecting the water-supply, advised the inhabitants to boil all water used for drinking. Recently a thorough inves-

tigation of this supply has been made by the Massachusetts State Board of Health, and, in a letter from its secretary to the Hyde Park Board, recommends the continuance of this precaution and the obtainment as soon as possible of a supply better protected from sources of contamination.

The continued recurrence of such epidemics serves only to re-emphasize the insidious dangers of typhoid fever and the seeming impossibility of its extermination by even the wisest sanitary provisions. At such a time the protective possibilities of anti-typhoid inoculation become all the more impressive. From all American army-posts where it is being employed come unanimously favorable reports of its safety, trifling discomfort and efficacy in reducing the incidence and mortality from typhoid. Education and example will be the most potent factors in persuading the public and the medical profession to the general adoption of this valuable prophylactic procedure.

A TYPHOID CARRIER.

A TYPHOID carrier, who was responsible for the death of two persons from typhoid fever and the illness of over thirty others during the past summer, has been discovered in the person of an Adirondack guide. A baffling outbreak of the disease, involving at least thirty-six persons, occurred in a fashionable camp in the Adirondack Mountains, and experts were called in to discover the cause. The water supply was found to be absolutely pure, but the milk, as used by the residents, proved to be contaminated. It was shown that this milk was originally of the finest quality and that it was gathered and delivered under all possible sanitary precautions. It was learned, however, that the last person who handled it was the guide referred to, and an investigation of this individual revealed the fact that he was suffering from chronic dysentery and was also a prolific producer of typhoid bacilli. The State Department of Health was appealed to, but declined to take any action, on the ground that there is no law in the state authorizing the health authorities to interfere in a case of this kind. It will be remembered that the notorious "Typhoid Mary" was kept secluded for more than two years on North Brother Island, but this was by the purely local action of the New York City Health Department. The man consented of his own accord, however, to come to New York, at the earnest request of Dr. Charles E. North, of the New York Milk Committee, and, if the money can be secured for his maintenance, Dr. North purposes giving him a thorough course of Metchnikoff lactic acid treatment, in the hope, possibly, of putting a stop to the production of typhoid germs.

MEDICAL NOTES.

FIRE IN A CANADIAN HOSPITAL. — Report from Toronto, Ont., states that on Dec. 1 the Toronto Free Hospital for Consumptives, at Weston, was destroyed by fire. The ninety-two patients in the hospital, of whom forty are helpless, were safely removed.

ASSOCIATION OF FOOD AND DAIRY DEPARTMENTS. — The annual convention of the National Association of State and National Food and Dairy Departments, which was held on Nov. 28 to Dec. 1 in New Orleans, La., was attended by representatives from nearly every state. One of the principal topics under discussion at the sessions was "The Uniformity of National and State Pure Food Laws."

DIPHTHERIA IN CHICAGO. — It is reported that diphtheria is epidemic in Chicago. On Nov. 27 there were about eight hundred cases in that city. Stringent measures have been taken to prevent further spread of the infection, and an additional sum of $10,000 has been voted to meet the expense of combating the disease.

HARVEY LECTURES. — The third lecture of the series of 1910–11 of the Harvey Society will be given in New York on Dec. 10 by Dr. Harvey Cushing, of Baltimore, Md., on "Certain Clinical Aspects of Dyspituitarism." The postponed lecture by Professor Castle will be given on Feb. 25, 1911.

SUSPENSION OF PUBLICATION OF THE *Montreal Medical Journal*. — It is announced that with its current December issue the *Montreal Medical Journal* will cease publication. It is understood that this is done through friendly agreement with the Canadian Medical Association, whereby the work hitherto done by the *Montreal Journal* will continue to be represented in a new publication.

DEPORTATION OF A CASE OF TRACHOMA. — In last week's issue of the JOURNAL, we referred to the case of an Armenian immigrant who, being ordered deported on account of having trachoma, appealed for a writ of habeas corpus on the ground that she had married an American citizen. This appeal has been denied by the United States Dis-

trict Court, and the woman will be deported unless she obtains a reversal of this decision before the Circuit Court of Appeals.

Epidemics of Cholera. — During the week ending Dec. 3, 27 new cases and only, 3 deaths of Asiatic cholera were reported from Italy, a slight decrease from the record of the preceding week. Report from Lisbon, Portugal, states that the disease is epidemic in Funchal, the capital of Madeira, but the number of cases is not given.

Movement against Opium in China. — There is apparently a definite movement in China against the sale and use of opium, except for medicine. Advices from Pekin state that on Dec. 2 the imperial senate passed a resolution forbidding the inter-provincial transportation of the drug after July, 1911, and its consumption by smoking after January, 1912. This resolution is said also to advocate abrogation of the opium treaty with Great Britain, thereby preventing further importation from India. The abolition of illegal opium traffic by oriental initiative seems, however, almost incredible; and one is tempted to mistrust the genuineness of reform from a habit of such long duration.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston.— For the week ending at noon, Dec. 6, 1910, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 42, scarlatina 27, typhoid fever 12, measles 24, smallpox 0, tuberculosis 56.

The death-rate of the reported deaths for the week ending Dec. 6, 1910, was 17.80.

Boston Mortality Statistics.—The total number of deaths reported to the Board of Health for the week ending Saturday, noon, Dec. 3, 1910, was 219, against 185 the corresponding week of last year, showing an increase of 34 deaths, and making the death-rate for the week, 16.95. Of this number 120 were males and 99 were females; 213 were white and 6 colored; 131 were born in the United States, 86 in foreign countries and 2 unknown; 52 were of American parentage, 137 of foreign parentage and 30 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 47 cases and 0 deaths; scarlatina, 31 cases and 0 deaths; typhoid fever, 15 cases and 0 deaths; measles, 27 cases and 1 death; tuberculosis, 59 cases and 25 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 24, whooping cough 6, heart disease 29, bronchitis 5. There were 17 deaths from violent causes. The number of children who died under one year was 31; the number under five years, 50. The number of persons who died over sixty years of age was 75. The deaths in public institutions were 70. Cerebrospinal meningitis, 2 cases. Anterior poliomyelitis, 2 cases.

Of the above infectious diseases the following were non-residents: Diphtheria, 1 case. Consumption, 4 cases and 3 deaths. Scarlet fever, 3 cases.

Deducting deaths of non-residents, the total is 189 and the death-rate is then 14.63.

Nomination of a Physician for the School Board. — Dr. Thomas F. Leen, of Boston, has been nominated by the Citizens' Municipal League and by the Public School Association as candidate for election to the Boston School Board.

Newly Registered Physicians. — Forty-one candidates, of whom two were women, passed the recent examination by the Massachusetts State Board of Registration in Medicine and are now entitled to practise under the laws of the commonwealth.

A Living Centenarian. — Richard K. Powers, of Lancaster, Mass., is locally reputed to have been born on Nov. 27, 1810, in Sterling, Mass. It is reported that he recently celebrated the supposed centennial anniversary of his birth by sawing cord wood in his back yard. He is said to attribute his longevity and good health to habitual vigorous physical exercise.

Appointment of School Physicians. — The Boston Board of Health recently recommended a reduction in number and an increase in salary of the school physicians in this city, of whom there are at present 80. It is now proposed by the mayor to increase this number to 115 and raise the salary of each physician from $200 to $300. Action on this proposition is still undecided.

Work of Industrial School. — The sixteenth annual report of the Massachusetts Industrial School for Crippled and Deformed Children, recently published, presents the record of the valuable work done by this institution during the past year. A year ago, the number of pupils was increased from thirty to thirty-five, and the opening of a new fourth schoolroom this fall makes possible the admission of about twenty-five more. A special appeal is made for additional contributions of money to enable the provision of

an open-air room for children of tuberculous susceptibility. The annual Christmas celebration and sale will be held at the school on Dec. 23.

SISTER RAPHAEL SUCCESSOR TO SISTER GONZAGA. — In an editorial in the issue of the JOURNAL for Nov. 24 we noted the retirement from the Carney Hospital, South Boston, of Sister Gonzaga, who was associated with the hospital for thirty years, and since 1881 had been its sister superior. Her successor, who has recently assumed charge, is Sister Raphael, formerly superior of St. John's Hospital, Lowell, Mass. Sister Raphel, who was born at Emmetsburg, Md., served as an army nurse during the Spanish War and has also been in Panama and in the West.

NEEDS OF MILK AND BABY HYGIENE ASSOCIATION. — In a communication to the public press, the treasurer of the Boston Milk and Baby Hygiene Association states that since the beginning of its fiscal year, June 1, 1910, the association has received subscriptions to the amount of nearly $8,700. There are at present 607 babies registered at the stations of the association. To complete the work of the current fiscal year there will be need of at least $7,400 more, for which earnest appeal is made to the public.

THE SCHOOL LUNCH PROBLEM. — At a conference held in Boston on Dec. 3 by the Woman's Educational and Industrial Union on the problem of the school luncheon, an address was made by Dr. George S. C. Badger, who pointed out that the unpalatable or unhygienic school lunch emanates as often from the home of the ignorant well-to-do as from that of the needy poor. Education of parents seems a wiser agent in securing proper nutrition of children than even discriminating free distribution of school luncheons by public or private charity. The risks of pauperization are even greater to society than those of malnutrition.

DECREASE OF TUBERCULOSIS IN BOSTON. — The seventh annual meeting of the Boston Association for the Relief and Control of Tuberculosis was held on Nov. 30. The reports of the officers described the activities of the Association during the past year. This year has seen the establishment by the Association of the Prendergast Camp for convalescent or arrested cases of phthisis, which cost over $5,000. During this year, also, there were given under the auspices of the Association 81 lectures, chiefly to labor unions, and over 4,500 anti-spitting cards and more than 35,000 other pieces of educational literature were distributed. Attention was called to the decrease in the total number of deaths from tuberculosis in Boston from 1,227 in 1903, the year in which the Association was organized, to 1,073 in 1909. Mr. Robert Treat Paine was elected president of the Association for the ensuing year, and Dr. Arthur K. Stone its vice-president.

NEW YORK.

A VICTIM OF THE FOLDING BED. — The folding bed has claimed another victim in New York. Benjamin Lott, a civil engineer, died on Dec. 1 in the Harlem Hospitals from injuries he had received the night previous by the sudden closing of a folding bed in which he and his wife were sleeping. There was a dislocation in the cervical vertebræ, caused by the sides of the bed which caught his neck and held it tight, and from the moment of the accident he was completely paralyzed from the seat of injury down. Mrs. Lott, who was thrown on her head, which was pressed between the mattress and the pillow, was nearly suffocated before she was rescued.

QUARTERLY MORTALITY REPORT. — The condensed quarterly report of the Bureau of Records of the City Health Department shows that in the quarter ending Sept. 30, 1910, there was a decrease of 2,165 in the total number of deaths from the average of the past five years. In almost all diseases there was a smaller mortality than the quinquennial average, and among the largest decreases from this average were the following: Diarrheal diseases under five years of age, 778; apoplexy and softening of the brain, 318; organic heart diseases, 171; Bright's disease and acute nephritis, 165; pulmonary tuberculosis, 136; simple meningitis, 111; pneumonia, 94; cerebrospinal meningitis, 80. Among the few increases from the quinquennial average were the following: Cancer, 49; chronic bronchitis, 5; influenza, 3.

LOW DEATH-RATE FOR NOVEMBER. — The low record in the death-rate reached in October was surpassed by the figures for November, the mortality in the city representing an annual death-rate of 13.89, as against 13.90 in the month of October and 15.04 in November, 1909. This is somewhat remarkable, as many of the diseases on the list show more or less increase in deaths. Among the diseases in which there was an augmented fatality were the following: The weekly average of deaths from measles increased from 2

in October to 4 in November; the weekly average from scarlet fever, from 2.5 to 5; from whooping cough, from 3.75 to 4.25; from diphtheria and croup, from 16.5 to 25.75; from influenza, from 1.5 to 3.25; from pulmonary tuberculosis, from 153.25 to 155; from acute bronchitis, from 11.75 to 19.5; from pneumonia, from 71.75 to 94.5; from bronchopneumonia, from 64.5 to 73.5; from apoplexy and softening of the brain, from 23.25 to 25.5; from organic heart diseases, from 112.25 to 137; and from Bright's disease and acute nephritis, from 88.75 to 108.25. Among the diseases in which there was a diminished mortality were the following: The weekly average of deaths from typhoid fever declined from 17.75 to 15.75; from epidemic cerebrospinal meningitis, from 5.5 to 2.75; from diarrheal diseases, from 143.25 to 65.5; from diarrheals under five years of age, from 133.75 to 57.5; from cancer, from 76.25 to 70; from appendicitis and typhlitis, from 14.25 to 8.25; and from puerperal diseases, including septicemia, from 10.5 to 8.75. In the week ending Nov. 26 but 5 deaths were reported from typhoid fever, the lowest number from this disease since the third week of May, last. The corrected death-rate for the month, excluding non-residents and infants under one week old, was 13.18.

6. Musser emphasizes the following facts in relation to enteroptosis: The high tension of modern life, especially of the leisure class, is especially productive of the symptoms encountered in enteroptoses. This condition is rarely found in the laboring classes. Victims of this neurosis are generally members of neurotic or degenerating families. These cases from childhood have poor health, especially noticeable in abdominal symptoms. Musser found no evidence of malnutrition or perverted nutrition or toxemia in the metabolic analyses of ten such cases and finds this additional evidence of the strong neurotic element in this condition. Operation often does great harm by calling attention more closely to the abdominal symptoms. If we could recognize congenital ptoses, as he believes these are, early enough, and before the neuroses develop, we might be able to forestall the ill-effects of the insufficiencies which develop later.

8. Marshall has done some very exhaustive experimental work on the bacterial flora of arthritic and non-arthritic cases, and, in endeavoring to adjust theories to the findings, advances the following to explain the intimate relation so commonly seen to exist between chronic arthritic cases and enteroptoses and intestinal stasis or inefficiency. As to the origin of the toxins, which are supposed to be the cause of the arthritic conditions, there are three theories: (1) Some specific organism that produces the toxic substance, which has not yet been discovered, is present in the stools. (2) Ordinary non-pathogenic bacteria develop excessively, and the products of their activities exert a mild irritating effect on joint tissues from being in excess in the blood. (3) Defective digestion produces abnormal chemical products independently of bacterial action that are the cause of arthritis. Examinations, however, of stools of arthritic patients show no constant characteristics or any pecularities that are not observed in patients who do not have arthritis. The relationship between intestinal toxins and joint lesions must depend on variable formation of toxins, variable absorption of them through the intestinal walls, variable unknown processes in their passage through the liver into the general circulation and diverse resistances of joint tissues. Production of toxins fluctuates with the quantity of nitrogenous food and the abundance of bacteria and hence may be diminished by changing the character of the diet and introduction of micro-organisms, such as lactic acid bacteria, which inhibit the growth of putrefactive bacteria. But patients with arthritis who respond to intestinal

treatment habitually eat more than their digestive tract is capable of handling, and intestinal putrefaction hence is apt to occur in excess. Excessive amounts of bacterial products from the intestines find their way into the blood and irritate susceptible joints. Hence through the regulation of the activities of the intestinal tract we have, in a certain per cent of cases, a means of favorably influencing arthritic conditions. [E. H. R.]

5. Fleisher and Loeb found that adrenalin injected intraperitoneally increases the rapidity of absorption of fluid from the peritoneal cavity, independently of whether the solution to be absorbed is hypotonic or hypertonic or is approximately isotonic with the blood serum. The intravenous injection of adrenalin also increases the absorption of fluid, but not so markedly as does the intraperitoneal injection. They also found that the increase of absorption from the peritoneal cavity caused by the injection of adrenalin is not due to the increased diureses caused by the injection of this substance.

10. Fowler and Hawk found that the daily drinking of three liters of water with meals for a period of five days by a young adult in nitrogen equilibrium produced an increase in body weight and an increased excretion of urinary nitrogen, but a decreased excretion of feces and of fecal nitrogen and a decrease in the quantity of bacteria excreted. They conclude that copious water drinking with meals stimulates protein catabolism and in general is attended by many desirable and by no undesirable features. [R. I. L.]

4. Fleisher and Loeb, in summarizing all the experiments in which they studied absorption from the peritoneal cavity, state that changes in the osmotic pressure of the blood represent the principal factor in explaining the variations in the rate of absorption of fluid from the peritoneal cavity. They find no direct relation between an increase in the rate of absorption of fluid from the peritoneal cavity and an increase in the amount of urine secreted. Under the influence of caffeine a greater amount of sodium chloride is eliminated from the body fluids into the tissues or through the kidneys. The writers believe that in the case of caffeine and other similar substances the diuresis is not due primarily to a specific action of the kidney, but to conditions which affect the distribution of sodium chloride in the body.

7. Wright calls attention to a group of tumors now usually classified as glioma, sarcoma, lymphoma or lymphosarcoma. The essential cells of the tumor are considered to be more or less undifferentiated nerve cells or neurocytes or neuroblasts and hence the names neurocytoma and neuroblastoma. Wright reports twelve cases from the literature and his personal experience. In a large proportion of the cases the adrenal was involved. Wright believes that inasmuch as five of the new cases have been recognized within the year, neurocytoma will not prove to be a very rare tumor. [R. I. L.]

7. Dickinson advocates Cæsarean section for impassable contraction ring under the following conditions: (1) Child living and not enfeebled or endangered by length of labor, long drainage of water or unskilled attempts at extraction. (2) Ring refusing to relax under morphia or to yield to complete etherization, coupled with patient manual dilatation by a skilled obstetrician. (3) Mother in fair condition for a laparotomy and not infected. (4) Request by patient and husband that a somewhat increased risk to the mother be assumed for the sake of obtaining a living child, in lieu of embryotomy. These indications are perfected if (5) at a previous labor, in expert hands, this same condition of the contraction ring has caused loss of a child not unduly large. There are six cases of section for contraction ring reported in available literature. All were in skilled hands. Of five instances, in only one was the section undertaken of choice. Three of the six mothers died. Two children survived. These, however, were all desperate cases and do not contra-indicate the advisability

of this operation with its now greatly lowered mortality. Dickinson goes carefully into the etiology, clinical picture, diagnosis and treatment of this condition in a most thorough manner.

9. Clark and Norris summarize their article on conservative surgery of the pelvic organs as follows: Practically all pelvic inflammatory cases should be given a course of preliminary treatment before operation. By this method some cases will escape operation entirely, while others can be operated more easily, quickly and safely. A greater number of cases will be found suitable for a conservative operation. If possible, four to six weeks of normal temperature and blood counts should precede each operation. Pus which can be easily reached without traversing the peritoneal cavity should be evacuated at once. The proportion of cases requiring emergency surgery is extremely small. The end results of salpingectomies are disappointing. Pregnancy rarely takes place. Conservation of macroscopically diseased tubes is, however, unsatisfactory. Conservative ovarian surgery offers excellent results provided the ovarian circulation is not impaired. The reason many resected ovaries become cystic is because of interference with blood supply. When it is found necessary to remove both ovaries, an hysterectomy should also be done. Such uteri are useless and often cause subsequent trouble. If it is necessary to remove the uterus, and one or both ovaries can be spared, their preservation will prevent the unpleasant symptoms of the artificial menopause. In the presence of myomata, hysteromyomectomy is the operation of choice in the great majority of cases. If it is possible to amputate across the cervix at such a level as to leave behind corporeal endometrium, scant but regular menstruation will follow if one or both ovaries are preserved. [E. H. R.]

5. FORDYCE, A. D. *The Care of the Infant and Young Child (to Five Years) in Edinburgh.*

1. Gibson reports the details of an interesting case in which thoracotomy was done to relieve the heart with adhesive pericarditis. In this particular case only temporary benefit ensued.

4. Wilkie has made a study of peptic ulcer of the jejunum occurring as a sequel to gastro-jejunostomy. He recognizes two types, one gastro-jejunal, in which the ulceration occurs at the site of the anastomosis, and the other true jejunal ulceration, in which one or more ulcers form in the jejunum at some distance from the anastomotic opening; the former is more common. It may manifest itself at any period after the operation from a few weeks to several years; it is usually associated with a recurrence of the gastric symptoms. The tendency to perforation of such ulcers is greater than in the case of gastric ulcer. In all recorded cases the original operation was done for non-malignant affection of the stomach or duodenum. Such ulceration has been met with in every variety of gastro-enterostomy; in the majority of cases the preceding gastric lesion had been associated with hyperacidity; it is probably caused by the action of the acid gastric juice or the jejunal mucosa normally exposed to an alkaline medium. He gives the details of three cases in which this ulceration had occurred and presents experiments on hyperacidity and jejunal ulcer. The article is well illustrated with numerous plates. [J. B. H.]

QUARTERLY JOURNAL OF MEDICINE. VOL. 4. NO. 13.

OCTOBER, 1910.

1. GIBSON, A. G., GOOD, T. S., AND PENNY, R. G. *The Pulse immediately Preceding the Epileptic Attack.*
2. *THURSFIELD, H. *Influenzal Septicemia, with a Short Review of the Present Status of Bacillus Influenzæ.*

7. *COWAN, J., AND RITCHIE, W. T. *Coupled Rhythms of the Heart.*
8. *WHITE, W. H. *The Outlook of Sufferers from Exophthalmic Goiter.*

2. Thursfield relates two cases of influenzal septicemia; the first resembled clinically a severe attack of grippe, with a temperature chart resembling that of croupous pneumonia; the second started with symptoms of phlebitis of the leg, followed by fever, consolidation in the lung, and dry pericarditis. Both cases ended in recovery and Pfeiffer's bacillus was obtained in pure culture from the blood in both. Leucocytosis was absent. He then reviews the rôle played by the influenza bacillus in disease. On the basis of Cohen's three cases of septicemic meningitis he concludes that this form is due to a variety of the bacillus which is pathogenic for animals, but this is not invariably so, for in a case coming under the observation of the reviewer, the bacillus was without effect when inoculated into suitable animals.

3. This article is a report of the study of the coagulation time of the blood in twelve hemophiliacs. Addis found that the delay in the coagulation time of the blood, which is always to be found in this disease, is roughly proportional to the severity of the symptoms, in the severe cases being prolonged even up to eighty minutes. The addition of thrombokinase to hemophilic blood hastened the coagulation time, but large amounts were necessary to render it normal. With small amounts, which were sufficient to decrease notably the coagulation time in normal blood, the hemophilic blood was still very slow in clotting. The amount of negative pressure necessary to produce bruising with a dry cup was found to be the same in a hemophiliac as in a normal person, which shows that fragility of the capillaries cannot be assumed in hemophilia. In short, the delayed clotting which is always present in hemophilia is sufficient of itself to account for all the phenomena.

5. The authors found in a case of acute endocarditis with prolonged a–c interval an inflammatory lesion of the auriculo-ventricular bundle, in another case with very short

a-c interval a similar lesion in the auriculo-ventricular node, without implication of the bundle.

6. Tuberous sclerosis is a rare developmental disease characterized by the presence of scattered hard nodules in the cerebral cortex, frequently associated with tumors in the heart, kidneys and skin. During life, epilepsy and imbecility are constant features. If, in addition to these, adenoma sebaceum is present, the diagnosis may be made *intra vitam*, otherwise not. The authors report one case and analyze the literature.

7. By coupled rhythm of the heart the authors mean that two beats are separated by a short pause, and the second beat is followed by a long pause. This is what most writers call bigeminy. Cowan and Ritchie describe the various forms of this condition, classifying it as follows: (1) Coupled rhythm of the ventricles, occurring at times in partial and complete heart-block in perpetual arrhythmia, and as a result of ventricular extrasystoles; (2) coupled rhythm of both auricles and ventricles. They illustrate these types by original tracings and discuss at length the various theories as to the method of production of the bigeminy.

8. White's statistical report of a large series of cases of Graves' disease merely shows that many such patients recover under medical treatment although in too poor condition to stand an operation. He considers that the most important feature in medical treatment is absolute rest in bed for weeks and months, with freedom from anxiety. [W. T.]

3. Zieler adds his experience with some fifty cases of syphilis early and late treated by Ehrlich's new compound. He is strong in his praise of the new preparation. He mentions, however, that it is still too early to be sure of the end results, but for temporary results it is far superior to mercury. Possibly in the future it will be found necessary to combine the two.

4. Koll describes in detail a method which he has devised for the long-continued (several hours) intravenous injection of adrenalin. He has tried it on animals and finds that it is a valuable means of keeping up blood pressure. He thinks it is practical for clinical medicine and surgery. [C. F., JR.]

12. *DIBBELT, W. *Disturbances of the Metabolism for Lime in Rachitis.* (Concluded.)

1. Bruns describes a simple apparatus for temporarily lowering the air pressure in the lungs. The essential parts of the apparatus are a pump and air tank to which a face mask is attached in such a way that the patient breathes in and out of the tank through the mask. The experiments seem to show that in this manner the suction of the great veins in the chest can be much increased, the diastole of the heart facilitated and the velocity of the circulation considerably increased. The method is recommended for cases in which cardiac embarrassment is due to improper functioning of the respiration, as in emphysema, kyphosis, and the like; and for cases of cardio-muscular weakness, as in obesity or anemia. The treatment may be given for about fifteen minutes at a time. It gives considerable relief and is liked by the patients. The contra-indications are the same as for other forms of physical therapy: severe decompensation, aneurysm, thrombosis and impending embolism, but it can safely be used in mild cardiac insufficiency.

3. Roth reaches the conclusion that, when the ordinary methods have failed, Hoffmann's method of injecting the N. laryng. sup. with alcohol is a safe and useful means of combating dysphagia resulting from tuberculosis of the larynx.

4. Having recently studied three cases of heart lesion following trauma, Beckhaus believes that it is more common than is generally supposed. He recommends after any severe accident, especially to the left side of the chest, that the heart be examined carefully, and that if cardiac symptoms should appear later, they be not hastily attributed to neurasthenia.

12. As a result of careful experimentation, Dibbelt has reached the conclusion that rachitis is a disturbance of the metabolism for calcium, that the excretion of calcium through the intestines is increased in rachitis, and that the bone changes are due to resorption. In explanation he offers the view that excessive excretion of calcium may be favored by food lying unabsorbed in the intestine as a result of illness in the child or artificial feeding of infants. [G. C. S.]

1. *Umber, F. *Observations on the Pathology and Treatment of Duodenal Ulcer.*
2. Baginsky, A. *General Principles in the Treatment of the Infectious Diseases of Children.*
3. *Weiss, O. *The State of the Present Theory Concerning Asthma.*
4. Jacobsohn, L. *The Importance of the Suprarenal Preparations in Medical Practice.*

1. Umber believes that duodenal ulcer occurs a good deal more frequently than it is diagnosed. He emphasizes the following important diagnostic symptoms: (1) Pain in the right parasternal line in the gall-bladder region, coming on not more than three hours after the ingestion of food, sometimes relieved by taking more food. In one case the writer observed attacks of severe paroxysmal pain in the knees and elbows; the ulcer was situated on the posterior wall of the duodenum and had eroded the head of the pancreas. (2) A palpable resistance at the seat of pain. (3) Chilly feelings in the hands, feet and abdomen. (4) Blood in the stools, the patient having been on a meat-free diet for several days and gastric analysis being negative. Umber advises operation for duodenal ulcer only when there are such urgent indications as profuse bleeding or unbearable pain.

3. Weiss correlates his clinical experience with Brügelmann's theory of the causation of asthma. The essential factor in producing an attack is an irritation of the respiratory center. Such irritation may be traumatic, reflex or toxic. Grief or terror or any other severe "cerebral trauma" may precipitate a typical asthmatic seizure. Reflex irritation may come from any part; toxic irritation from disease or excess of CO_2. [L. D. C.]

Revue de Médecine.

October, 1910.

1. *Bernheim. *Venous Asystole in Hypertrophy of the Left Heart, due to Concomitant Stenosis of the Right Ventricle.*
2. *De Brun. *Studies on Paludal Infantilism.*
3. Stcherbach. *Litteral Psychomotor Hallucinations and Other Phenomena due to the Excitation of the Cortical Centers of Letters in Jacksonian Epilepsy.*

1. According to the observations of Bernheim upon ten cases with autopsy, the condition of right ventricular collapse is not rare. Hypertrophy or dilatation of the left heart is not often associated with a dilatation of the entire right heart, as has been formerly supposed. The hypertrophy of the interventricular septum and its convex bulging into the right ventricle, from dilatation, produces a stenosis of the lower half of that cavity. Above this point there is dilatation of the upper part of the ventricle and the right auricle, with all the signs of stasis of the great circulation. This phenomenon accounts for the frequency, in cardiac insufficiency, of congestion of the abdominal organs, ascites, etc., without evidence of the least interference with the lesser circulation — in the lungs.

2. De Brun reports forty cases of a peculiar type of infantilism, which he considers due to faulty metabolism, provoked by a chronic malarial infection. The subjects are short of stature, with thin extremities, small head and extremely infantile external genital organs. Pubic and axillary hair is generally wanting and the voice is shrill and high pitched. The author believes that this failure to develop, mentally as well as physically, is due to (1) absence of testicular or ovarian internal secretion; (2) sclerosis of the thyroid with consequent hypothyroidism; (3) atrophy of the pituitary gland and; (4) atrophy of the suprarenals. All the cases presented evidence of the first, while others showed during life or post-mortem characteristic malarial sclerosis of the thyroid. Isolated cases presented symptoms and signs similar to acromegaly and Addison's disease. It seems most reasonable that there should be some common etiological factor for so many very similar cases. [L. H. S.]

Obituary.

SAMUEL ALEXANDER, M.D.

Dr. Samuel Alexander, a prominent New York surgeon, died Nov. 29, at the New York Hospital, after an operation for appendicitis. He belonged to the well-known Alexander family of Princeton, N. J., and was fifty-one years of age. He was a graduate from Princeton University in 1879 and from Bellevue Hospital Medical College in 1882. He afterwards served as interne in Bellevue Hospital, and in 1887 became visiting surgeon to the hospital, a position which he retained up to the time of his death. He was also surgeon to the Montefiore Home and Hospital for Chronic Invalids. He was for some time a lecturer at the Bellevue Hospital Medical College, and in 1900 was appointed professor of clinical surgery, Department of Diseases of the Genito-Urinary System, in Cornell University.

There are but few men in the profession whose deaths could bring so deep a sense of loss to those of its members who knew him as that of Dr. Alexander.

His abundant vitality and enthusiasm, his keen and clear habit of thought and expression, his directness, his absolute honesty, the whole-hearted devotion to his work and the ardent energy with which he threw himself into it, inspired and stimulated all who came in contact with him. To the students whom he helped to equip for their careers, he imparted much of his own zeal and the desire to attain to the goals he placed before them; veterans felt their forces renewed and drew from his presence something of the sense of exuberant life which was never absent from him and which lent such warmth and color to all that he said and did.

More than any one of our number that we call to mind, he possessed the quality which, for lack of a better name, we term personal magnetism. He drew and held his pupils as a magnet draws and holds bits of steel, and his unconscious exercise of this power, applied as it always was to further scientific knowledge and to impart it to his scholars, to maintain and to promote the highest standards of professional work, exerted

in these directions a potent and most valuable influence. Medical education in this country by his death is deprived of one of its most striking figures, and suffers a serious loss.

He was easily the most brilliant as well as one of the ablest of the group of men whose work lies in the special field of surgery to which he devoted himself. To many of the members of the Genito-Urinary Association the first thought when preparing to go to the annual meetings of the association to which he, and they, belonged was the pleasure of seeing him again, of listening to the sharp, terse, incisive sentences in which he put forward his views upon the various questions that were under discussion, and the certainty they felt of being filled with new enthusiasm and with the desire to strive to reach yet higher levels than those they had yet reached, which they knew would result from their contact with him.

He made many men his debtors in such ways as these, and as one of them, the writer desires to do homage to his memory.

Correspondence.

THE ADVISABILITY OF THE ESTABLISHMENT OF A STATE HOSPITAL FOR CASES OF NERVOUS BREAKDOWN.

BROOKLINE, MASS., Dec. 5, 1910.

Mr. Editor: In an article on page 822 of the JOURNAL of Nov. 24, 1910, under the heading, "Desirability of a State Psychopathic Hospital," I am misrepresented as remarking upon the "disadvantages" of a state psychopathic hospital at a recent hearing at the State House. As such an institution is now in process of construction, and as I, in common with other physicians, worked early and late to secure this admirable means for the early treatment of mental disease, the reporter's mistake is obvious.

The matter under consideration at the hearing was the advisability of the establishment of quite a different institution, namely, a sanitarium or hospital for cases of nervous breakdown and other nervous conditions not amounting to insanity. Of the great need of such a provision, there is no doubt in my mind. The principal question is whether the work should be entered upon under state or private auspices, a matter which is still *sub judice*. For some inexplicable reason my comment at the hearing on the various advantages and disadvantages of both plans was taken by the reporter to refer to a psychopathic hospital.

Very truly yours,
HENRY R. STEDMAN, M.D.

[The use of the adjective "psychopathic" in the title and in the first line of the piece of Miscellany on page 822 of the JOURNAL of Nov. 24 seems to have given rise to some confusion in the minds of some of our readers, and in so far was unfortunate. Such a misunderstanting of our statement on the part of these readers was not anticipated at the time the contribution was printed. — ED.]

SOCIETY NOTICE.

THE NEW ENGLAND HOSPITAL MEDICAL SOCIETY. — This society will meet at the Kensington Chambers, corner Boylston and Exeter streets, Boston, Room 203, on Thursday, Dec. 15, at 7.30 P.M. Section of Obstetrics, Dr. Sarah R. Stowell, chairman. Subject: "The Progress in Obstetrics," Dr. Franklin S. Newell.

BLANCHE A. DENIG, M.D.,
Secretary.

RECENT DEATHS.

DR. LANDON B. EDWARDS, who died at Richmond, Va., on Nov. 27, was born in 1845. He was a charter member of the Medical Society of Virginia, a founder of the Virginia Medical Monthly Journal and of the University College of Medicine in Richmond. He had practised in the latter city for many years.

DR. WILLIAM F. HUSSEY, who died of heart disease last week at Roslindale, was born in East Boston on June 29, 1881. He graduated from the Tufts Medical School in 1905, served a year in the Marine Hospital at Chelsea, Mass., and subsequently studied for a time in Vienna. He was a member of The Massachusetts and of the Norfolk County Medical Societies.

DR. HENRY HUTCHINSON, of St. Paul, Minn., who died of heart disease on Dec. 2, at Algiers, was born in Montreal, Canada, on Aug. 20, 1849. In 1874 he graduated from the Hahnemann Medical College at Philadelphia, and after practising four years in Northfield, Minn., settled in St. Paul. In 1894 he became a member of the Minnesota State Board of Health, and since 1901 had been its president. He was for a time professor of theory and practise in the College of Homeopathic Medicine and Surgery, University of Minnesota. He was a member of the American Health Association, of the Minnesota State Anti-Tuberculosis Association, and of the American and Minnesota Institutes of Homeopathy.

DR. FREDERICK D. MCNEAL, who died of pneumonia last week in Troy, Ohio, was born in 1840. He was at one time food and dairy commissioner of Ohio.

DR. CHARLES TESSIER, who died last week of cerebral hemorrhage at Haverhill, Mass., was born in Canada in 1853. He is survived by two daughters and by one son, also a physician.

DR. BENJAMIN WILLIAMS, of Rockland, Me., who died at Prospect Harbor, Me., on Nov. 27, was born in 1835. During the Civil War he served as assistant surgeon of the Eighth Maine Regiment.

DR. THOMAS GILL NOCK, a well-known physician and former mayor of Rome, N. Y., died on Nov. 28, in his fifty-second year. He was a native of Windsor, Conn., and was graduated from the College of Medicine, Syracuse University, in 1883. He had served as coroner of Oneida County and as a manager of the State Hospital for the Insane at Utica, and for the past six years was a member of the board of fire and police commissioners of Rome.

RECORD OF MORTALITY

Address.

PHYLOGENETIC ASSOCIATION IN RELATION TO CERTAIN MEDICAL PROBLEMS.*

BY G. W. CRILE, M.D., CLEVELAND, OHIO.

THE discovery of the anesthetic properties of ether and its practical application to surgery must always stand as one of the great achievements of medicine. It is eminently fitting that the anniversary of that notable day, when the possibilities of ether were first made known to the world, should be celebrated within these walls, and whatever the topic of your Ether Day orator, he must fittingly first pause to pay tribute to that great event and to the master surgeons of the Massachusetts General Hospital. On this occasion, on behalf of the dumb animals as well as on behalf of suffering humanity, I express a deep sense of gratitude for the blessings of anesthesia. Two years ago an historical appreciation of the discovery of ether was here presented by Professor Welch, and last year an address on medical research was given by President Eliot. I, therefore, will not attempt a general address, but will present an experimental and clinical research.

Time will permit the presentation of only the summaries of the large amount of data. The great assistance rendered by my associates, Dr. D. H. Dolley, Dr. H. G. Sloan, Dr. J. B. Austin and Dr. M. L. Menten,[1] I acknowledge with gratitude.

The scope of the title of this paper may be explained by a concrete example.

When a barefoot boy steps on a sharp stone there is an immediate discharge of nervous energy in his effort at escape from the wounding stone. This is not a voluntary act. It is not due to his own personal experience (i. e., his ontogeny), but is due to the experience of his progenitors during the vast periods of time required for the evolution of the species to which he belongs, i. e., his phylogeny. The wounding stone made an impression upon the nerve receptors in the foot similar to the innumerable injuries which gave origin to this nerve mechanism itself during the boy's vast phylogenetic or ancestral experience. The stone supplied the phylogenetic association, and the appropriate discharge of nervous energy automatically followed. If the sole of the foot is repeatedly bruised or crushed by the stone, shock may be produced. If the stone be only lightly applied, then there is also a discharge of nervous energy from the sensation of tickling. The body has had implanted within it in a similar manner other mechanisms of ancestral or phylogenetic origin whose purpose is the discharge of nervous energy for the good of the individual. In this paper I shall discuss the origin and mode of action of some of these mechanisms including certain phases of anesthesia.

The word anesthesia — meaning *without feeling* — describes accurately the effect of ether in anesthetic dosage. Although no pain is felt in operations under inhalation anesthesia, the *nerve impulses set up* by a surgical operation still reach the brain. We know that not every portion of the brain is fully anesthetized, since surgical anesthesia does not kill. The question then is, What effect has trauma under surgical anesthesia upon the part of the brain *that remains awake?* If, in surgical anesthesia, the traumatic impulses cause an excitation of those wide-awake cells, are the remainder of the cells of the brain, despite anesthesia, influenced in any way? If influenced, they are prevented by the anesthesia from expressing the same in conscious perception or in muscular action. Whether the *anesthetized* cells are influenced or not must be determined by noting the physiologic function after anesthesia has worn off, and in animals by an examination of the brain cells as well. It has long been known that the vasomotor, the cardiac and the respiratory centers discharge energy in response to traumatic stimuli applied to various sensitive regions of the body during surgical anesthesia. If the trauma is sufficient, exhaustion of the entire brain is observed after the effect of the anesthetic is worn off; that is to say, despite the complete paralysis of voluntary motion and the loss of consciousness due to ether, the traumatic impulses that are known to reach the *awake* centers in the medulla also reach and influence every other part of the brain. As to whether or not the consequent functional depression and the morphologic alterations seen in the brain cells may be due to the low blood pressure which follows excessive trauma is answered by the following experiments, viz.: the circulation of animals was first rendered *static* by over-transfusion, and was controlled by a continuous blood-pressure record on a drum, the factor of anemia was thereby wholly excluded during the application of the trauma and during the removal of a specimen of brain tissue for histologic study. In every such instance morphologic changes in the cells of all parts of the brain were found, but it required more trauma to produce *equal* morphologic changes in animals protected against low blood pressure than in animals whose blood pressure gradually declined in the course of the experiments.

In the cortex and in the cerebellum, the changes in the brain cells were in every instance more marked than in the medulla. There is also strong *negative* evidence that traumatic impulses are not excluded by ether anesthesia from the part of the brain that is apparently asleep. This evidence is as follows:

If the factor of fear be excluded, and if in addition the traumatic impulses are prevented from reaching the brain by cocain blocking, then, despite the intensity or the duration of the trauma within the zone so blocked, there follows no exhaustion after the effect of the anesthetic disappears, and no morphologic changes are noted in the brain cells. A still further negative evidence that inhalation anesthesia offers little or no protection to the brain cells from trauma is derived

* Address delivered at the Massachusetts General Hospital on the sixty-fourth anniversary of Ether Day, Oct. 18, 1910.

[1] From the H. K. Cushing Laboratory of Experimental Medicine, Western Reserve University, Cleveland.

from the following experiment: A dog whose spinal cord had been divided at the level of the first dorsal segment, and then kept in good condition for two months, showed a recovery of the spinal reflexes, such as the scratch reflex, etc. This animal is known as a "spinal" dog. Now, in this animal the abdomen and hind extremities have no direct nerve connection with the brain. In such a dog a continuous severe trauma of the abdominal viscera and of the hind extremities lasting four hours was accompanied by but slight change in either the circulation or in the respiration, and no microscopical alteration of the brain cells. Judging from a large number of experiments on *normal* dogs under ether, such an amount of trauma would have caused not only a complete physiologic exhaustion of the brain, but also morphologic alterations of all of the brain cells and physical destruction of many. We must, therefore, conclude that, although ether anesthesia produces unconsciousness, it *apparently protects none of the brain cells* against exhaustion from the trauma of surgical operations; ether is, so to speak, but a veneer. Under nitrous oxide anesthesia there is approximately only one fourth the exhaustion on equal trauma as under ether; either nitrous oxide protects or ether predisposes to exhaustion under trauma. With this as a point of departure we will inquire into the cause of this exhaustion of the brain cells.

ON THE CAUSE OF THE EXHAUSTION OF THE BRAIN CELLS FROM TRAUMA OF VARIOUS PARTS OF THE BODY UNDER INHALATION ANESTHESIA.

Numerous experiments on animals upon the effect of ether anesthesia *per se*, i. e., ether anesthesia without trauma, showed that although certain changes were seen there was neither the characteristic physiologic exhaustion after the anesthesia had worn off nor were there seen the characteristic changes in the brain cells. Turning to trauma, in a study of the behavior of individuals as a whole under deep and under light anesthesia, we at once found the cue to the discharge of energy, — the consequent physiologic exhaustion and the morphologic changes in the brain cells.

If, in the course of abdominal operations, rough manipulation of the parietal peritoneum is made, there is frequently observed a marked increase in the respiratory rate and an increase in the expiratory force, even to the extent of an audible expiratory groan. Under light ether anesthesia severe manipulation of the peritoneum often causes such vigorous contractions of the abdominal muscles that the operator may be greatly hindered in his work.

Among the unconscious responses to trauma under ether anesthesia are purposeless moving, withdrawing of the injured part, and if the anesthesia is sufficiently light and the trauma sufficiently strong, there may be an effort directed toward escape from the injury. In injury under ether anesthesia every grade of response may be seen, from the slightest change in the respiration or in the blood pressure to a vigorous defensive struggle. As to the purpose of these subconscious movements in response to injury, there can be no doubt, — *they are efforts at escape from the injury.*

Can any one picture the actual result of a formidable abdominal operation extending over a period of half an hour or more in an unanesthetized human patient if extensive adhesions are broken up, or if a large tumor is dislodged from its bed? In such a case would not the nervous system discharge its energy to the utmost in efforts to escape from the injury, and would the patient not suffer complete exhaustion? If the traumata, under inhalation anesthesia, be sufficiently strong and repeated in sufficient numbers, the brain cells will finally be deprived of their dischargable nervous energy and become exhausted just as exhaustion follows a strenuous and too prolonged muscular exertion, for example, such as is seen in endurance tests. Whether the nerve energy of the brain is discharged by injury under anesthesia, or whether by ordinary muscular exertion, identical morphologic changes are seen in the nerve cells. In shock from injury, in exhaustion from overwork (Hodge and Dolley) and in exhaustion from pure fear, the general functional weakness is similar, — in each a certain length of time is required to effect recovery, and in each there are morphologic changes in the brain cells. It is quite clear that in each of these cases the altered function and form of the brain cells are due to an *excessive discharge of nervous energy*. This brings us to the next question, viz., what determines the discharge of energy from trauma with or without inhalation anesthesia?

ON THE CAUSE OF THE DISCHARGE OF NERVOUS ENERGY FROM TRAUMA IN ANIMALS UNDER INHALATION ANESTHESIA AS WELL AS IN THE NORMAL STATE WITH SPECIAL REFERENCE TO MEDICAL PROBLEMS.

I looked into this problem from many viewpoints and there seemed to be no solution until it occurred to me to seek the explanation in certain of the postulates which make up the doctrine of evolution. I realize fully the difficulty and the danger in attempting to reach the generalization which I shall make later and in the hypothesis I shall propose. There is, of course, no direct final proof of the truth of even the doctrine of evolution. It is idle to consider any experimental research into the cause of phenomena that have by natural selection required millions of years to develop. Nature has made the experiments on a world-wide scale; the data are before us for interpretation. Darwin could do no more than collect all available facts and then frame an hypothesis that best harmonized the facts. Sherrington, that masterly physiologist, in his volume entitled "The Integrative Action of the Nervous System," shows clearly how the central nervous system was built up in the process of evolution. Sherrington has made free use of Darwin's doctrine in explaining physiologic functions, just as anato-

mists have extensively utilized it in the explanation of the genesis of anatomical forms. I will assume, therefore, that the discharge of nervous energy is accomplished by the application of the law of inheritance and association, and that this hypothesis will explain many clinical phenomena. I shall present such evidence in favor of this hypothesis as time and my limitations will admit, after which I shall point out certain clinical facts that may be explained on this hypothesis.

According to the doctrine of evolution, every function owes its origin to natural selection in the struggle for existence. In the lower and simpler animal life, indeed, in our human progenitors as well, existence depended principally upon the success with which three great purposes were achieved, viz., (1) self-defense against or escape from enemies; (2) the acquisition of food; and (3) procreation; and these were virtually the only purposes for which nervous energy was discharged. In its last analysis in a biologic sense this statement holds for man of to-day. Disregarding for the present the expenditure of energy for procuring food and for procreation, we will consider the discharge of energy in self-preservation. The mechanisms for self-defense which we now possess were developed in the course of vast periods of time from the lowest forms through all the intermediary stages to our present estate. One would expect, therefore, that we are now in possession of mechanisms which still may discharge energy on adequate stimulation but are not suited to our present needs. We shall point out such examples. As Sherrington has stated, there is interposed between ourselves and the environment in which we are immersed, our skin, in which are implanted many receptors for receiving specific stimuli which are transmitted to the brain. When these stimuli reach the brain, there is a specific response principally in the form of muscular action. Now, each receptor can only be adequately stimulated by the particular factor or factors in the environment which created the necessity for the receptor in question. Thus there have arisen receptors for touch, for temperature, for pain, etc. The receptors for pain have been designated noci-ceptors (nocuous or harmful influences) by Sherrington.

On the basis of natural selection, only the regions of the body that have been during long periods of time exposed to injury could have developed noci-ceptors. On this ground the finger, because it is exposed, should have many noci-ceptors, while the brain, though the most important organ of the body, because it has been during a vast period of time protected by a skull, should have no noci-ceptors. Realizing that this point is a crucial one, Dr. Sloan and I made a series of careful experiments. The cerebral hemispheres of dogs were exposed by removal of the skull and dura under ether anesthesia and under local anesthesia. Then various portions of the hemispheres were slowly but completely destroyed by rubbing with a piece of gauze. In some instances the hemisphere was destroyed by burning. In no instance was there more than a slight response of the centers governing circulation and respiration, and there was no morphologic change noted in an histologic study of the brain cells of the uninjured hemisphere. The experiment was as completely negative as the experiments on the "spinal" dog. Clinically I have confirmed the experimental findings in the course of explorations for brain tumor with a probe in conscious patients. Such explorations elicited neither pain nor evidence of altered physiologic functions. The brain, therefore, contains no mechanism, — no noci-ceptors, — the direct stimulation of which could cause a discharge of nervous energy in a self-defensive action. That is to say, direct injury of the brain can cause no purposeful nerve muscular action, while direct injury of the finger does cause purposive nerve muscular action. In like manner, the deeper portions of the spinal region have been sheltered from trauma, and they too show but little power of causing a discharge of nervous energy on receiving trauma. The various tissues and organs of the body are differently endowed with injury receptors, or the noci-ceptors of Sherrington. The abdomen and chest when traumatized stand first in their facility for causing the discharge of nervous energy, i. e., *they stand first in shock production*. Then follow the extremities, the neck and the back. It is an interesting fact that *this* physical type or *that* physical type of trauma elicits different responses as to the discharge of energy. Because it is such a commonplace, one scarcely realizes the importance of the fact that clean-cut wounds with a razor-like knife cause the least reaction, while a tearing, crushing trauma causes the greatest response. It is a suggestive fact that the technic of the carnivora in fighting each other and in killing their prey is probably the most efficient shock-producing trauma known. *In the course of evolution this may well have been the predominating type of trauma to which our progenitors were subjected.* In one particular respect there is an analogy between the response to trauma of some of the parts of the body of the individuals of a species susceptible to shock and the response to trauma of certain of the great divisions of the animal kingdom. Natural selection has protected one great division, the crustacea, against its enemies with a protective armor — the turtle and the armadillo are examples; to another division — the birds — it has given a sharp eye and wings, — the wild goose is an example; to another it has given a diabolic odor for protection, — the skunk is an example. The turtle, protected by its armor, is in a very similar position with respect to its protection against trauma as the sheltered brain of man, and like the brain does not respond by an especially active self-protective nerve muscular response. The turtle merely withdraws its head and legs within the armored protection and is proverbially difficult to exhaust or to kill by trauma. The brain and other phylogenetically sheltered parts likewise cause no exhausting self-protective nerve muscular response. The skunk is quite effectively protected from violence by its peculiar odor. This is indicated not only by con-

sidering the protective value of the odor, but also by the fact that the skunk has no efficient nerve muscular mechanism for escape or defense, and can neither run fast nor can it climb a tree. Moreover, in encounters it shows no fear and backs rather than runs. The armadillo rolls itself into a ball for defense. Therefore the turtle, the armadillo and the skunk should have fewer noci-ceptors than a dog or man and should show less response to trauma. On the evidence of two (an insufficient number) carefully conducted experiments on the skunk, and two on the armadillo, there was as compared with the dog, the opossum, the pig, the sheep and the rabbit very much less discharge of energy on severe and protracted trauma of the abdominal viscera. These subjects were indeed relatively difficult to exhaust by trauma. These experiments are too few to be conclusive but they are of some value and furnish an excellent lead. It seems more than a coincidence that fear, noci-ceptors and susceptibility to shock go hand in hand in these comparative observations.

The discharge of energy caused by an adequate mechanical stimulation of the noci-ceptors is best explained in accordance with the law of phylogeny and association. That is, injuries awaken such reflex actions as have by natural selection been developed for the purpose of self-protection. Adequate stimulation of the noci-ceptors for pain is not the only means of causing a discharge of nervous energy. Nervous energy may also be discharged by adequate stimulation of the various ticklish regions of the body. The entire skin surface of the body contains delicate ticklish receptors. These receptors are closely related to the noci-ceptors for pain, and their adequate stimulation by an insect-like touch causes a discharge of energy — a nerve muscular reaction — resembling that of brushing off insects. This reflex is similar to the scratch reflex elicited in the dog. This discharge of energy is almost wholly independent of the will and is a self-protective action in the same sense as is the response to pain stimuli. The ear in man and in animals is acutely ticklish, — the adequate stimulus being any foreign body, — especially a buzzing insect-like contact. The discharge of nervous energy in horses and in cattle on adequate stimulation of the ticklish receptors of the ear is so extraordinary that in the course of evolution it must have been of great importance to the safety of the animal. A similar ticklish zone guards the nasal chambers. The discharge of energy here takes such form as effectively to dislodge the foreign body. The larynx is exquisitely ticklish, and in response to adequate stimulus, energy is discharged in the production of a vigorous cough. The mouth and pharynx have active receptors which cause the rejection of nocuous substances. The conjunctival reflex, though not classed as ticklish, is a most efficient self-protective reflex. I assume that there is no doubt as to the meaning of the adequate stimuli and the nerve-muscular response of the various ticklish receptors of the surface of the skin, of the ear, the nose, and the eye, and the larynx. These mechanisms were developed by natural selection as protective measures against the intrusion of insects and foreign bodies into regions of great importance. The discharge of energy in these instances is in accordance with the law of inheritance and association. The other ticklish points which are capable of discharging vast amounts of energy are the lateral chest wall, the abdomen, the loins, the neck and the soles of the feet. The type of adequate stimuli of the soles of the feet, the distribution of the ticklish points upon them, and the associated response leave no doubt that these ticklish points were long ago established as a means of protection from injury. Under present conditions they are of little value to man.

The adequate stimulus for the ticklish points of the ribs, the loins, the abdomen and the neck is deep isolated pressure, probably the most adequate being that of a tooth-shaped body. The response to tickling in these regions is actively and obviously self-defensive. The horse discharges energy in the form of a kick; the dog wriggles and makes a counter-bite; the man makes efforts at defense and escape.

There is strong evidence that the deep ticklish points of the body were acquired through vast periods of fighting, with teeth and claws. Even puppies at play bite each other in their ticklish points and thus give a recapitulation of their ancestral battles and of the real battles to come. The mere fact that animals fight effectively in the dark and always according to the habit of their species supports the belief that the fighting of animals is not an intellectual but a reflex process. There is no book of rules governing the conduct of a fight between animals. The sequences of events follow each other with such kaleidoscopic rapidity that the process is but a series of automatic stimulations and physiologic reactions. Whatever the significance, it is certain that man did not come either accidentally or without purpose into possession of the deep ticklish regions of his chest and abdomen. Should any one doubt the vast power that adequate stimulation of these regions possess in causing the discharge of energy, let him be bound hand and foot and vigorously tickled for an hour. What would happen? He would be as completely exhausted as though he had experienced a major surgical operation or as if he had run a Marathon race.

A close analogy to the reflex process in the fighting of animals is shown in the rôle played by the sexual receptors in conjugation. Adequate stimulation of these two distinct groups of receptors, the noci and the sexual, cause specific behavior, — the one toward embrace, the other toward repulsion. Again, one of the most peremptory causes of the discharge of energy is that due to an attempt forcibly to obstruct the mouth and the nose, threatening asphyxia. Neither friend nor foe is trusted, and a desperate struggle for air ensues. It will be readily granted that the efforts to prevent suffocation were established for the purpose of self-preservation, but the discharge of nerve-muscular energy to this particular end is

no more specific and no more shows adaptative qualities than do the preceding examples. . Even the proposal to bind one down hand and foot excites resentment, a feeling of self-preservation. No patient views with equanimity the application of shackles preparatory to anesthesia for an operation.

We have now considered some of the causes of the discharge of nervous energy due to various types of harmful physical contact, and have suggested analogous though antithetical sexual receptors. The response to the adequate stimuli of each of the several receptors is a discharge of nerve muscular energy of a specific type: One type for the ear, one for the larynx, one for the pharynx, another for the nose, another for the eye, another for the deep ticklish points of the chest and the abdomen, quite another for the delicate tickling of the skin, and still another in response to sexual and to painful stimuli.

According to Sherrington, a given receptor has a low threshold for only one, its own — hence a specific stimulus and a high threshold for all others; that is, the doors that guard the nerve paths to the brain are opened only on receiving the proper password. According to Sherrington's law, the individual as a whole responds to but one stimulus at a time, that is, only one stimulus occupies the nerve paths which perform acts, i. e., the final common path. As soon as a stronger stimulus reaches the brain it dispossesses whatever other stimulus is then occupying the final common path, — the path of action. The various receptors have a definite order of precedence over each other (Sherrington). For example, the impulse from the delicate ticklish points of the skin whose adequate stimulus is an insect-like contact could not successfully compete for the final common path with the stimulus of a noci-ceptor. The stimulus of a fly on the nose would be at once superseded by the crushing of a finger. In quick succession do the various receptors (Sherrington) occupy the final common path, but each stimulus is for the time always the sole possessor, hence the nervous system is integrated (connected up) to act as a whole. Each individual at every moment of its life has a limited amount of dischargeable nervous energy. This energy is at the disposal of any stimulus that obtains possession of the final common path, i. e., the *performance of acts*. Each discharge of energy is subtracted from the sum total, and whether the subtractions are made by the excitation of noci-ceptors by trauma, by tickling, by fighting, by fear, by flight, or by the excitation of sexual receptors, singly or in combination, the sum total of expenditure of energy, if large enough, produces exhaustion. Apparently there is no distinction between that state of exhaustion which is due to the discharge of nervous energy in response to trauma and that due to other causes. The manner of the discharge of energy is specific for each type of stimulation. On this conception traumatic shock takes its place as a natural phenomenon and is divested of its mask of mystery.

THE DISCHARGE OF ENERGY THROUGH STIMULATION OF THE DISTANCE RECEPTORS, OR THROUGH REPRESENTATION OF INJURY (PSYCHIC).

We will now turn from the discussion of the discharge of nervous energy by mechanical stimuli to the discharge of energy through mental perception. *Phylogenetic* association may arise through the distance receptors as well as through physical contact, viz., through sight, hearing, smell, or by a representation of physical experiences. The effect upon the organism of the representation of injury or of the perception of danger through the distance receptors is designated *fear*. Fear is as widely distributed in nature as is its cause, that is, fear is as widely distributed as injury. Animals under the stimulus of fear, according to W. T. Hornaday, not only may exhibit preternatural strength, but also show strategy of the highest order, a strategy not seen under a lesser stimulus. In some animals fear is so intense that it defeats escape; this is especially true in the case of birds in the presence of snakes. The power of flight has endowed the bird with an easy means of escape from snakes, especially when the encounter is in the tops of trees. Here the snake must move cautiously else he will lose his equilibrium. His method of attack is by stealth. When the snake has stalked its prey, the bird is often so overcome by fear that it cannot fly and so becomes an easy victim. The phenomena of fear are described by Darwin as follows:

"Fear is often preceded by astonishment and is so near akin to it that both lead to the senses of sight and hearing being instantly aroused. In both cases the eyes and mouth are widely opened and the eyebrows raised. The frightened man at first stands like a statue motionless and breathless, or crouches down as if instinctively to escape observation. The heart beats quickly and violently, so that it palpitates or knocks against the ribs. That the skin is much affected under the sense of fear, we see in the marvelous and inexplicable manner in which perspiration immediately exudes from it. This exudation is all the more remarkable as the surface is then cold, and hence the term, 'a cold sweat'; whereas the sudorific glands are properly excited into action when the surface is heated. The hairs also on the skin stand erect, and the superficial muscles shiver. In connection with the disturbed action of the heart, the breathing is hurried. The salivary glands act imperfectly; the mouth becomes dry and is often opened and shut. I have also noticed that under slight fear there is a strong tendency to yawn. One of the best-marked symptoms is the trembling of all the muscles of the body, and this is often first seen in the lips. From this cause, and from the dryness of the mouth, the voice becomes husky and indistinct, or altogether may fail. As fear increases into agony of terror, we behold, as under all violent emotions, diversified results. The heart beats wildly, or may fail to act, and faintness ensue; there is a death-like pallor; the breathing is labored; the wings of the nostrils

are dilated; there is a gasping and convulsive motion of the lips, a tremor on the hollowed cheek, a gulping and catching of the throat; the uncovered and protruding eyeballs are fixed on the object of terror, or they may roll restlessly from side to side. The pupils are said to be enormously dilated. All the muscles of the body become rigid, or may be thrown into convulsive movements. The hands are alternately clenched and opened, often with a twitching movement. The arms may be protruded, as if they were to avert some dreadful danger, or may be thrown wildly over the head. In other cases there is a sudden and uncontrollable tendency to headlong flight; and so strong is this, that the boldest soldier may be seized with a sudden panic. As fear arises to an extreme pitch, the dreadful scream of terror is heard. Great beads of sweat stand on the skin. All the muscles of the body are relaxed. Utter prostration soon follows, and the mental powers fail. The intestines are affected. The sphincter muscles cease to act and no longer retain the contents of the body. Men during numberless generations have endeavored to escape from their enemies or danger by headlong flight, or by violently struggling with them; and such great exertions will have caused the heart to beat violently, the breathing to be hurried, and the chest to heave, and the nostrils to be dilated. As these exertions have often been prolonged to the last extremity, the final result will have been utter prostration, pallor, perspiration, trembling of all the muscles, or their complete relaxation. And now, whenever the emotion of fear is strongly felt, though it may not be from any exertion, the same results tend to reappear, through the force of inheritance and association." (*Darwin.*)

In an experimental research, we found evidence that the physiologic phenomena of *fear* have a physical basis. This evidence is morphologic alterations in the brain cells, similar to certain stages of surgical shock and in fatigue from muscular exertion. For the present we will assume that fear is a *representation* of trauma. Because fear was created by trauma, fear causes a discharge of the energy of the nervous system on the law of phylogenetic association. The almost universal fear of snakes, of blood and of death and dead bodies may have such a phylogenetic origin. It was previously stated that under the stimulus of fear animals show preternatural strength. An analysis of the phenomena of fear shows that, so far as can be determined, all of the functions of the body requiring the expenditure of energy and which are of no direct assistance in the effort toward self-preservation are suspended. Involuntary expenditure of muscular energy, such as in the chase, the suspension of other functions is by no means so complete. Fear, hence trauma, may, therefore, drain to the last dreg the dischargeable nervous energy; therefore, the greatest possible exhaustion may be produced by fear and trauma. This is a distinction between fear and desire.

There is a factor, however, that influences the discharge of energy which I must discuss briefly. I refer to summation.

SUMMATION.

In the discharge of energy, summation plays an important rôle. Summation is attained by the repetition of stimuli at such a rate that each succeeding stimulus is applied before the nerve cells have returned to the resting stage from the preceding stimulus. If drops of water fall upon the skin from a sufficient height to cause the slightest unpleasant sensation, and at such a rate that before the effect of the stimulus of one drop has passed another drop falls in precisely the same spot, there will be felt a gradually increasing painful sensation until it becomes unbearable. This is summation. When a patient requires for a long time frequent painful wound dressings, there is a gradual increase in the acuteness of the pain receptors. This is summation. In a larger sense the behavior of the entire individual gives considerable evidence of summation, e. g., in the training of athletes the rhythmic discharge of muscular energy at such intervals that the resting stage is not reached before a new exercise is given results in a gradual ascent in efficiency until the maximum is reached. This is summation, and summation plays a large rôle in the development of both normal and pathologic phenomena.

We have now pointed out the manner in which at least a part of nervous energy of man may be discharged. The integrative action of the nervous system and the discharge of nervous energy by phylogenetic association may be illustrated by the analogy of an electric automobile. The electric automobile is composed of three principal parts: the motor and the wheels (the muscular system and the skeleton); the cells of the battery containing stored electricity (brain cells, nervous energy); and the controller which is connected with the cells by wiring (the receptors and the nerve fibers); and an accelerator button for increasing the electrical discharge (thyroid gland [?]). The machine is so constructed that it acts as a whole for the accomplishment of a single purpose. When the controller is adjusted for going ahead (adequate stimulus of a receptor), then the conducting paths (the final common path) for the accomplishment of that purpose are all open to the flow of the current from the battery, and the vehicle is integrated to go ahead. It spends its energy to that end and is closed to all other impulses. When the controller is set for reverse, the machine is by this adequate stimulus integrated to back, and the battery is closed to all other impulses. Whether integrated for going forward or backward, if the battery be discharged at a proper rate until exhausted, the cells, though possessing no more power (fatigue), have sustained no further impairment of their elements than that of normal wear and tear. Furthermore, they may be restored to normal activity by recharging (rest). If the vehicle be placed against a stone wall, and the controller be placed at top speed ahead (trauma and fear), and if the accelerator is on as well (thyroid secretion?), though the machine will not move, the battery will not

only soon be exhausted, but the battery elements themselves will be seriously damaged (exhaustion, — surgical shock).

We have now presented some evidence that nervous energy is discharged by the adequate stimulation of one or more of the various receptors that have been developed in the course of evolution. In response to an adequate stimulus, the nervous system is integrated for the specific purpose of the stimulated receptor, and but one stimulus at a time has possession of the final common path, — the nerve mechanisms for action. The most numerous receptors are those for harmful contact. These are the noci-ceptors. The effect of the adequate stimulus of a noci-ceptor is like that of pressing an electric button that sets in motion great machinery.

With this conception, the human body is likened to a musical instrument, — an organ, the keyboard of which is composed of the various receptors upon which environment plays the many tunes of life; and written within ourselves in symbolic language is the history of our evolution. The skin may be the "Rosetta Stone" which furnishes the key.

ANOCI-ASSOCIATION.

We are now prepared on the law of phylogenetic association to make a practical application of the principles of the discharge of nervous energy. In the case of a surgical operation, if fear be excluded and if the nerve paths between the field of operation and the brain be blocked with cocaine, there will be no discharge of energy due to the operation; hence, there can be no shock, no exhaustion. Under these conditions of operation the nervous system is protected against noci-association whether by noci-perception or by an adequate stimulation of noci-ceptors. The state of the patient in whom all noci-associations are excluded can be described only by coining a new word. That word is "*anoci-association.*"

The difference between anesthesia and anoci-association is that although *inhalation anesthesia* confers the beneficent loss of consciousness and freedom from pain, it does not prevent the nerve impulses from reaching and influencing the brain, and hence does not prevent surgical shock nor the train of later nervous impairments so well described by Mumford. *Anoci-association* excludes fear, pain, shock and post-operative neuroses. *Anoci-association* is accomplished by a combination of special management of patients (applied psychology), morphine, inhalation anesthesia and local anesthesia.

We have now presented in summary much of the mass of experimental and clinical evidence we have accumulated in support of our principal theme, viz., that the discharge of nervous energy is accomplished by the law of phylogenetic association. If this point seems to have been labored, it is because we expect to rear upon this foundation a clinical structure. How does this hypothesis apply to surgical operations?

PREVENTION OF SHOCK BY THE APPLICATION OF THE PRINCIPLE OF ANOCI-ASSOCIATION.

Upon this hypothesis a new principle in operative surgery is founded, viz., operation during the state of *anoci-association.* Assuming there is no unfavorable effect of the anesthetic, and no hemorrhage, the nerve cells of the brain cannot be exhausted in the course of a surgical operation except by fear, or trauma, or by both. Fear may be excluded by narcotics and special consideration until the patient is rendered unconscious by inhalation anesthesia. Then in addition to inhalation anesthesia, blocking with cocaine the nerve paths between the brain and the field of operation will place the patient in the beneficent state of *anoci-association,* and at the completion of the operation the patient will be as free from shock as at the beginning. In so-called "fair risks" such precautions may not be necessary, but in cases handicapped by infections, by anæmia, by previous shock and by Graves' disease, etc., anoci-association may become vitally important.

GRAVES' DISEASE.

Applying the principle of the discharge of nervous energy by phylogenetic association, and on the additional hypothesis that in the discharge of nervous energy the thyroid gland is, through the nervous system, stimulated, we can explain many phenomena of Graves' disease and possibly supply some of the factors to explain both the genesis and the cure of the disease.

In the wild state of animal life in which only the fittest survive in the struggle for existence, every point of advantage may have selection value. An animal engaged in battle or in a desperate effort at escape will be able to give a better account of itself if it has some means of accelerating the discharge of energy, some influence like that of oil upon the kindling fire. There is evidence, though perhaps not conclusive, that such an influence is exerted by the thyroid gland. This evidence is as follows: In myxedema, a condition characterized by a lack of thyroid secretion, there is a dullness of reflexes, and of intellect, a lowered muscular power, and generally a sluggish discharge of energy. In Graves' disease there is an excessive production of thyroid secretion. In this disease the reflexes are greatly sharpened, energy is discharged with very greatly increased facility, and metabolism is at a maximum. The same holds true in the administration of thyroid extract in large doses in normal subjects. In the course of sexual activities there is an increased action of the thyroid as indicated by an increased size and vascularity of the thyroid. In fear and in injury in cases of Graves' disease the thyroid is probably stimulated to increased activity as indicated by the increased activity of the thyroid circulation, by an increase in the size of the gland, by presenting the histologic appearance of activity in the nucleus of the cells, and by an increase of the toxic symptoms. Finally, Asher has stated that electric stimulation of the nerve supply of the thyroid causes an increased secretion. The origin

of many cases of Graves' disease is closely associated with some of the causes of the discharge of nervous energy, especially depressive influences, such as nervous shocks, worry and nervous strain, disappointment in love, business reverses, illness and death of relatives and friends. The association of activity of the thyroid with procreation is well known, hence the incidence of the double strain of overwork or of fear and the sexual evolution in maturing girls is obviously favorable to the development of Graves' disease. The presence of a colloid goiter is a suitable soil for the development of Graves' disease. I fully recognize the evidence that infection or auto-intoxication may be contributing factors and must be assigned their rôle.

I have never known a case of Graves' disease to develop from success or from happiness alone, nor from hard physical labor, unattended by strain, nor from the results of energy voluntarily discharged. Some cases seem to have had their origin in over-dosage of thyroid extract in too vigorous an attempt to cure a colloid goiter. In Graves' disease one of the most striking characteristics is the patient's loss of control and an increased susceptibility to stimuli, especially to trauma and to fear and to the administration of thyroid extract. It has been shown that the various causes of the discharge of nervous energy produce alterations in the nervous system and probably in the thyroid gland. This is especially true of the fear stimulus. This is clearly demonstrated in the brains of rabbits subjected to fear alone. Of special interest is the effect of daily fright. In this case the brain cells show a distinct change, although the animal is subjected to no fear for twenty-four hours before it is killed. Now, a great distinction between man and the lower animals is the greater control man has acquired over his actions. This quality of control, having been phylogenetically most recently acquired, is the most vulnerable to various *nocuous* influences. The result of a constant noci-integration may be a wearing out of the control cells of the brain. In Graves' disease there has been demonstrated in a typical case a marked morphologic change in the brain cells. As previously stated, the origin of many cases of Graves' disease is associated in a broad sense with some noci-influence. If this influence causes stimulation of both the brain and the thyroid, its excessive action may cause impairment of the brain and hyperplasia of the thyroid as well. As self-control is impaired, fear obtains ascendency and, *pari passu*, would stimulate the thyroid still more actively. Finally, the fear of the disease itself becomes a noci-stimulus. As the thyroid secretion causes an increase in the facility for the discharge of nervous energy, there is established a pathologic reciprocal interaction between the brain and the thyroid. The effect of the constantly recurring stimulus of the noci-influence is heightened by summation. This reciprocal goading may continue until either the brain or the thyroid is destroyed. If the original noci-stimulus is withdrawn before the fear of the disease becomes too strong, and before too much injury to the brain and the thyroid has been inflicted, a spontaneous cure may result. Cure may be greatly facilitated by a complete rest cure. A cure implies the return of the brain cells to their normal state, with the re-establishment of the normal self-control, and the restoration of the thyroid to its normal state. Then the impulses of daily life will once more have possession of the final common path and the noci-influence be dispossessed. The discovery of the real cause of a given case of Graves' disease is frequently difficult because the exciting cause may be personal and is painful. Of extreme interest is the fact that the patient in the acute stage may be unable to refer to the real cause without exhibiting an exacerbation of the symptoms of the disease. I presume no case should be regarded as cured until reference can be made to the cause without an abnormal reaction. It has been established that in Graves' disease injury to any part of the body even under inhalation anesthesia causes an exacerbation of the disease. Fear alone may cause an acute exacerbation. These acute exacerbations are frequently designated "hyperthyroidism" and are the special hazard of operation.

In operating on subjects of Graves' disease on the principle of anoci-association, there is scarcely a change in the pulse, in the respiration or in the nervous state at the close of the operation. Against the effect of the inflowing stimuli from the wound after the cocaine has worn off I know no remedy. It is necessary, therefore, in the serious cases not to venture too far. Since the adoption of this new method (anoci-association) my operative results have been so vastly improved that I now regard no case of Graves' disease as inoperable, at least to the extent of making a double ligation.

If we believe that a continuous stimulation of both the brain and the thyroid gland, on the law of phylogenetic association, accelerated by summation, plays a rôle in the establishment of the pathologic interaction seen in Graves' disease, then it is but the next step to assume that if the nerve connection between the brain and the thyroid is severed, or if the lobe is excised and the patient is reinforced by a sojourn in a sanatorium, or some environment free from former noci-association, the patient will, providing the brain cells, the heart or other essential organs have not suffered irreparable damage, be restored to normal health. There are still many missing links, and the foregoing is not offered as a final solution, although many of the phenomena from the viewpoint of the surgeon are explicable.

SEXUAL NEURASTHENIA.

The state of sexual neurasthenia is in many respects analogous to that of Graves' disease. In the sexual reflexes summation leads to hyper-excitability to psychic and mechanical stimuli of a specific type analogous to the hyper-excitability in Graves' disease to trauma and fear; both are based on the law of the discharge of energy by phylogenetic association and summation. It

would be interesting to observe the effect of interrupting the nerve impulses from the field of the sexual receptors by injections of alcohol or other agencies and thus exclude the associational stimuli until the nervous mechanism has again become restored to the normal.

INTERPRETATION OF SOME OF THE PHENOMENA OF CERTAIN DISEASES OF THE ABDOMEN ON THE HYPOTHESIS OF PHYLOGENETIC ASSOCIATION.

On the law of phylogenetic association, it is probable that many of the phenomena of certain lesions in the abdominal cavity become explicable. The noci-ceptors in the abdomen, like noci-ceptors elsewhere, have been established by some kind of injury to which this region has been frequently exposed over vast periods of time. On this premise, we could at once predict that there are no noci-ceptors for heat within the abdomen because during countless years the intra-abdominal region has not come in contact with heat. That this inference is correct is shown by the fact that the application of a thermocautery to the intestines when completing a colostomy in a conscious patient is absolutely painless. One could also predict the fact that there are no touch receptors in the abdominal viscera, hence no sense of touch in the peritoneum. Just as the larynx, the ear, the nose, the sole of the foot and the skin have all developed the specific type of noci-ceptors which are adapted for their specific protective purposes, and when adequately stimulated respond in a specific manner on the law of phylogenetic association, so the abdominal viscera have developed equally specific noci-ceptors as a protection against specific nocuous influences. The principal harmful influences to which the abdominal viscera may have been long exposed are deep tearing injuries by teeth and claws in the course of the innumerable struggles of our progenitors with each other and with their enemies; the perforation of the intestinal tract from ulcers, injuries, appendicitis, gallstones, etc., causing peritonitis; and over-distention of the hollow viscera from various forms of obstruction. Whatever may be the connection, it is a fact that the type of trauma from fighting corresponds nicely to that which in the experimental laboratory causes the most shock. Division of the intestines with a sharp knife causes no pain, but pulling on the mesentery elicits pain. Likewise, ligature of the stump of the appendix causes sharp cramp-like pains. Sharp division of the gall bladder causes no pain, but distention, which is the gall bladder's most common pathologic state, produces pain. Distention of the intestine causes great pain, but sharp cutting or burning causes none. In the abdominal viscera, like the superficial parts, noci-ceptors have been presumedly developed by specific harmful influences, and each noci-ceptor is open to stimulation only by the particular type that produced it.

As we have just stated, pain is associated with the excitation of noci-ceptors, and these may take precedence over and dispossess the routine functions, such as peristalsis, secretion and absorption, of their occupancy of their respective nervous mechanisms, just as fear does. Hence, the loss of weight, the lassitude, the indigestion, the constipation and the many alterations in the function of the various glands and organs of the digestive system in chronic appendicitis, chronic gall-bladder disease, may be explained. This hypothesis readily explains the extraordinary improvement in the digestive functions and the general health following the removal of an appendix so slightly altered physically that only the clinical results in many cases could persuade one that this change could be an adequate cause for such far-reaching and important symptoms. It would equally explain certain gall-bladder phenomena — the indigestion, loss of weight, disturbed functions, etc. This hypothesis may supply the explanation of the disturbance from an active anal fissure, which is a potent noci-associator, and the consequent disproportionate relief after the trivial operation for its cure. Noci-association would well explain the great functional disturbances of the viscera immediately following abdominal operations.

Post-operative and traumatic neuroses are at once explained on the ground of noci-association, with the resulting strain upon the brain cells, causing in them physical lesions. If one were placed against a wall and were looking into the gun muzzles of a squad of soldiers and were told that he must not be afraid because in nine chances out of ten he would not be killed outright when the volley was fired, would it help him to be told that he must not be afraid? Such an experience would be written indelibly on his brain. Yet this is much the same position in which some surgical patients are placed. In railway wrecks we can readily understand the striking difference between the conscious passenger and the sleeping or drunken one. In the latter persons the noci-perceptors and receptors were not aroused, hence their immunity. In the functional disturbances of the pelvic organs association and summation may play a large rôle. On this hypothesis many cases of neurasthenia may well be explained. In the behavior of the individual as a whole summation may well be a scientific expression for "nagging." Many other pathologic phenomena may be explained in a similar manner. Thus we can better understand the variation of a gastric analysis in a timid patient alarmed over his condition and afraid of the hospital. He is integrated by fear, and fear taking precedence over all other impulses, no organ functionates normally. On the same ground, one sees animals in captivity pine away under the dominance of fear. The exposure of a sensitive brain to the naked possibility of death from a surgical operation is equal to uncovering a photographic plate in the bright sunlight to inspect it before putting it in the camera. This principle explains, too, the physical influence of the physician or surgeon who, by his *personality*, inspires, like a Kocher, absolute confidence in his patient. The brain through its power of phylogenetic association controls many processes that

have wholly escaped from the notice of the "practical man." It is on the law of association that a flower, a word, a touch, a cool breeze, or even the thought of a fishing rod or of a gun, are helpful. On the contrary, any fragment of associational evidence of despair or misfortune, whether it be the corrugated brow, the gloomy silence of despair, a doubtful word, is equally depressing, and so could one add indefinitely to the symbolism that governs our daily lives. Thus, we see that through the law of inheritance and noci-association, we are able to read into the behavior of various diseases a new meaning.

OBSERVATIONS ON PATIENTS WHOSE ASSOCIATIONAL CENTERS ARE DULLED, AND ON DISEASES AND INJURIES OF REGIONS NOT ENDOWED WITH NOCI-CEPTORS.

Reversing the order, let us glance at the patient who is unconscious and who, therefore, has lost much of the power of association. His mouth is usually dry, the digestive processes are at a low ebb, the aroma of food causes no secretion of saliva. Tickling the nose causes no sneezing; he catches no cold. The laryngeal reflex is lost and food may be quietly inhaled. The entire process of metabolism is low. The contrast between man with associational centers keen and man with these centers dulled or lost is the contrast between life and death. On the behavior of the individual without associational power much might be said.

On the laws of adaptation through natural selection, phylogeny and association, one should expect no pain in abscess of the brain, in abscess of the liver, in pylephlebitis, in infection of the hepatic vessels, in endocarditis. This law explains why there are no noci-ceptors for cancer, and active noci-ceptors for the acute infections, because against cancer nature has no helpful response to offer and in certain of the acute pyogenic infections the noci-ceptors give the beneficent physiologic rest.

Could we dispossess ourselves of the shackles of psychology, and forget its confusing nomenclature, and view the human brain, as Sherrington has said, "as the organ of, and for, the adaptation of nervous reaction," many clinical phenomena would appear in a clearer light.

NATURAL SELECTION AND CHEMICAL NOCI-ASSOCIATION IN THE INFECTIONS.

Heretofore we have considered the behavior of the individual as a whole in response to a certain type of noci-influences. We have been thinking in terms of physical escape from *gross* physical dangers, or grappling with *gross nerve-muscular* enemies of the same or of other species, as related to some problems in medicine. To explain these phenomena we have invoked the aid of the laws of natural selection and phylogenetic association. If our conclusions are correct, then it should follow that in the same laws we can find the explanation of immunity, which, of course, means a defensive response to our *microscopic* enemies. There should be no more difficulty in building up by natural selection an efficient army of phagocytes, or specific chemical reactions against *microscopic enemies*, than the building up of the various noci-ceptors for our muscular defense against our *gross enemies*. That immunity is a chemical reaction is no hindrance to the application of the law of natural selection nor of association. What essential difference is there between the chemical defense of the skunk against its *nerve-muscular* enemies and its chemical defense (immunity) against *its microscopic enemies*?

The administration of vaccines becomes the adequate stimuli by phylogenetic association of a chemical nature whereby immune bodies are produced.

While mentioning this subject I will only raise the question whether or not the specific character of the inaugural symptoms of some infectious diseases may not be due to phylogenetic association. These inaugural symptoms are measurably a recapitulation of the leading phenomena of the disease in its completed clinical picture. Thus the furious immediate phenomena of pneumonia, of peritonitis, of erysipelas, of the exanthemata, show phenomena of exaggeration which are analogous to the phenomena of physical injury and of fear of physical violence. Just as the acute phenomena of fear or the adequate stimulus of noci-ceptors are a recapitulation of phylogenetic struggles, so may the inaugural symptoms of infections be a similar phylogenetic recapitulation of the course of the disease. A certain amount of negative evidence is supplied by the difference between the response of a dose of toxins as compared with a dose of a standard drug. No drug in therapeutic dosage except the iodine compounds causes a febrile response; no drug causes a chill; all specific toxins cause febrile responses, and many cause chills. If a species of animal had been poisoned by a drug over vast periods of time, and if natural selection had successfully established a self-defensive response, then the administration of that drug would cause the noci-association (chemical), and a specific reaction analogous to that following Coley's toxins might be expected. Bacterial noci-association probably operates through the same law as the physical contact of environment does. But natural selection is impartial. It must be supposed that it acts upon the microscopic invader just as well as upon the host. On this ground one would infer that the bacteria of acute infections must have met by natural selection each advance of the immunity of the host by the same law of natural selection. Hence, the fast and furious struggle between man and his microscopic enemies merely indicates to what extent natural selection has developed the *attack* and the *defense* respectively. This is analogous to the quick and decisive battles of the carnivora when fighting among themselves or when contending against their ancient enemies. But when phylogenetically strange animals meet each other, they do not understand how to conduct a fight. Natural selection has not had the opportunity of teaching them. The acute infections have the characteristics of being ancient enemies. On this hypothesis one might under-

stand the high mortality of measles when introduced into a new country. The infecting agency of measles by natural selection has become a powerful enemy of the human race, but the particular race to whom this infection is newly introduced has not had the equal advantage of building up its defense by the same law — natural selection. The variation in the effect of auto- and iso-pollution of water may be explained in a similar manner. Immunity and food assimilation are, therefore, on equal footing. May not the phenomena of anaphylaxis be studied on associational lines? Then, too, there may be chemical noci-associations of enemies now extinct, which like the ticklish points may still be active on adequate stimulation. This brief reference to the possible relation of the phenomena of the acute infections to the laws of natural selection and specific chemical noci-association has been made as a suggestion. Since the doctrine of evolution is all or nothing, I have included many phenomena to see how reasonable or unreasonable such an explanation might be.

RECAPITULATION.

The following are the principal points presented: In operations under inhalation anesthesia the nerve impulses from the trauma reach every part of the brain, — the cerebrum that is apparently anesthetized as well as the medulla that is known to remain awake, the proof being the *physiologic* exhaustion of and the *pathologic* change in the nerve cells. Under ether anesthesia the damage is at least four times greater than under nitrous oxide. Inhalation anesthesia is, therefore, but a veneer, a mask that "covers the deep suffering of the patient." The cause of the exhaustion of the brain is the discharge of nervous energy in a futile effort to energize the paralyzed muscles in an effort at escape from the injury just as if no anesthetic had been given. The exhaustion is, therefore, of the same nature as that from overexertion.

But if the nerve paths connecting the field of operation and the brain be blocked, then there is no discharge of nervous energy from the trauma, and consequently no exhaustion however severe or prolonged the operation.

Fear is a factor in many injuries and operations. The phenomena of fear probably are exhibited only by animals whose natural defense is nerve-muscular. The skunk, the porcupine, the turtle, have little or no fear. Fear is born of the innumerable injuries in the course of evolution. Fear, like trauma, may cause physiologic exhaustion of and morphologic changes in the brain cells. The representation of injury, which is fear, being elicited by phylogenetic association, may be prevented by the exclusion of the noci-association or by the administration of drugs like morphine and scopolamine, which so impair the associational function of the brain cells that immunity to fear is established. Animals whose natural defense is muscular exertion, among which is man, may have their dischargeable nervous energy used up by fear alone, by trauma alone, but most effectively by the combination of both. What is the mechanism of this discharge of energy? It is the adequate stimulus of the noci-ceptors — the electric buttons — and the physiologic response for the purpose of self-preservation. According to Sherrington, the nervous system responds in action as a whole and to but one stimulus at a time. The integration of the individual as a whole occurs not alone in injury and fear, but also, though not so strong, under other phylogenetic associations, such as the chase and procreation. When adequate stimuli are repeated in such a rhythm that the new stimulus is received before the effect of the previous one has worn off, a higher maximum is reached than is possible under a single stimulus, however powerful.

Sexual receptors are implanted into the body by natural selection, and the adequate stimuli excite the nerve muscular reactions of conjugation in a manner analogous to the action of the adequate stimulus of the noci-ceptors. The specific response of either the sexual receptors or the noci-ceptors is at the expense of the total amount of nervous energy available at the moment. Likewise, daily labor, which, in the language of evolution, is the chase, expends nervous energy. However, under the dominance of fear or injury the integration is most nearly absolute and probably every expenditure of nervous energy not required for efforts at self-preservation is arrested; hence fear and injury drain the cup to the dregs. This is the potential difference between fear and desire, between injury and conjugation.

What is the practical application of this? In operative surgery there is introduced a new principle, which removes from surgery much of the immediate risk from its trauma by establishing *anoci-association;* it places on a physical basis certain of the phenomena of fear; it explains to us the physical basis for the impairment of the entire individual under worry or misfortune; the daily noci-associations of the individual as a social unit; or a noci-influence of a part of the body. On the other hand, it explains the power of therapeutic suggestion and other influences which serve for the time to change the noci-integration, the physical basis for the difference between hope and despair; it explains some of the phenomena of Graves' disease, of sexual neurasthenia, possibly of hay fever and the genesis of the common cold. The principle is probably equally applicable to the acute infections whose chemical noci-association gives rise to many of the phenomena of the disease and explains their cure by natural immunity and by vaccines; it should teach us to view our patients as a whole; and especially should it teach the surgeon gentleness. It should teach us that there is something more in surgery than mechanics; and something more in medicine than physical diagnosis and drugs.

CONCLUSION.

The brain cells have existed during eons of time and amid the vicissitudes of change with perhaps less alteration than the crust of the earth. Whether lodged in man or in the lower animals,

they are related to and obey the same general biological laws, thus binding them, that is, ourselves, to the entire past and perform their function on the law of phylogenetic association.

So long have we directed our attention upon tumors, infections and injuries that we have not sufficiently considered the vital force itself. We have viewed each anatomical and pathologic part as an entity, and man as an isolated phenomenon in nature. May we not find in the law of adaptation under natural selection, and the law of phylogenetic association, the master key that will open to us the explanation of many of the pathologic phenomena as they have already explained many normal phenomena?

And may medicine not correlate the pathologic phenomena of the sick man with the forces of evolution, as the naturalists have correlated the phenomena of the sound man, — and disease as well as health be given its evolutionary setting?

THE TUBERCULOSIS PROBLEM AS APPLIED TO CHILDREN.*

BY JOHN B. HAWES, 2D, M.D., BOSTON.

THE subject of tuberculosis is such a large one and a campaign against it involves so many important undertakings that a given community, city, state or country must devote its energies to one or two vital issues and put off until later others of nearly equal importance. In this state, for instance, a sanatorium for early cases seemed to be of first importance; next, as it became evident that in order to check the disease consumptives must be taken away from the homes of the population until they are cured or until they have learned how to live at home, the three new sanatoria at North Reading, Lakeville and Westfield were built. These sanatoria are primarily for adult consumptives; they have as yet no suitable provision for children.

The state has not forgotten, but none the less has scarcely yet touched upon, the question of tuberculosis as it occurs in children. In Europe, especially in France, the reverse is the case. There, most attention has been given to the care and education of tuberculous children. The state of Massachusetts already has more beds for its adult consumptives in proportion to its population than any other. It is rapidly realizing, and I might say already realizes, that the next step must be to make proper provision for tuberculous children, or, of infinitely more importance, to educate and care for them so that they do not become tuberculous. In certain respects this is a far easier task than that of caring for adult consumptives. Any one who has had practical experience in this matter recognizes only too well the almost hopeless task of trying to train and educate in the rules of hygiene and right living ignorant, stupid people from the slums of our cities, especially if they cannot even speak or understand the English language. Children, however, are easily trained and can just as well be taught right ways of living in the school as to learn wrong ways at home.

The objection may be raised that open pulmonary tuberculosis is comparatively rare among children. While it is true that the number of children with active open pulmonary tuberculosis is small, the number of ill-nourished and anemic children who will become tuberculous unless they are taught how to live is very great. It has become a habit to call such children "pre-tuberculous." This word, now so much in use, is a somewhat unfortunate one. We are most of us tuberculous, or at least 60 to 90% of us are. Practically every one of us has somewhere a focus of tuberculosis, happily latent, taken into the body in the early days of childhood. Thus, strictly speaking, only children in the first or second year of life may be said to be "pre-tuberculous." A more correct form would be "pre-phthisical" or "pre-consumptive." What the word really means is simply that any child who is weak, anemic or run down from any cause stands a very good chance of either having his own latent focus of tuberculosis break out and become active, or of becoming the abiding place of some wandering tubercle bacilli.

Of the total number of consumptives, those cases which occur in children probably do not amount to more than 1%. This, at least, has been my experience in looking over the applications for admission to our state sanatoria during the past year. The number of children attending our public schools, however, who are in the so-called "pre-tuberculous" stage has been found to amount to 10 to 25% of the total number. In Paris, some years ago, Professor Grancher, in an investigation of over 6,000 school children, found that about 18% were in this condition; in Boston the percentage was found to be somewhat higher, — nearly 25%, — and elsewhere the average is 15 to 25%. It is for such children that our open-air schools, fresh-air rooms, etc., are intended. A child with active tuberculosis of the lungs should not go to any kind of a school, but should be sent to a sanatorium or hospital and be treated for his lung condition; if at such an institution he can be given some instruction as well, so much the better. At the present time there is practically no state institution where such children can be sent. It is to be hoped that the state will take immediate measures to meet this need.

Coming to that other class of children, those in the pre-tuberculous stage, we find the situation only slightly more encouraging. What has been accomplished so far has been done either by private organizations or by a few cities. There are two open-air schools in Massachusetts, one in Boston and one in Cambridge. The credit of establishing the first open-air school in this country belongs to Providence, R. I. Soon after this, such a school was opened in Boston, at first under the auspices of the Boston Association for the Relief

* Read before the annual meeting of the Springfield Anti-Tuberculosis Association, Nov. 9, 1910.

and Control of Tuberculosis, but later taken over by the Consumptives' Hospital Department of the City of Boston.[1] It is now planned to have an "open-air room" in each school in the city, and thus to give a far greater number of children the benefit of this treatment.

Of greater importance, however, than a single open-air school in a city, or a few fresh-air rooms in our schoolhouses, is the question of proper ventilation and sufficient fresh air for all of our schoolchildren. It is surely a very poor policy to wait until a child has become run down and anemic before we decide that what the child needs is fresh air. We are coming to realize that the health of our children is of greater importance than the development of their brains. An open-air school will do a great deal of good to a small number of children, but it will do a far greater good in proving to the city authorities and to the public at large that well children as well as sick children need and must have fresh air.

We are doing only a small part of our work, however, if we stop at providing open-air schools or fresh-air rooms. We must not only give the children fresh air at school, but we must teach them how to live in their homes. This is the most important part of our work. In 1908 a law was passed by the legislature that tuberculosis and its prevention should be taught in our public schools. This law met with considerable disfavor and has accomplished practically nothing. In very few places has active work been done in instructing children in "tuberculosis and its prevention," or in other matters of health and hygiene. There are a few striking examples, however, of excellent work in this direction, particularly in Salem and in Fall River. In Salem, school children have been given talks on the subject of how to live, and how to avoid tuberculosis and other diseases, and have written short essays on what they have learned. Some of these I have read, and I was very much impressed with the knowledge shown on this subject. In Fall River a similar work is being carried on in the schools, particularly by means of a school tuberculosis exhibit. This consisted of a number of separate pictures, mottoes, etc., hung up in the schoolroom, demonstrating certain fundamental truths of hygiene and health.

Last year a bill was introduced into the legislature by the Tuberculosis Committees of The Massachusetts Medical Society to authorize a small appropriation for the formation of school tuberculosis exhibits. This bill was approved and signed by Governor Draper. Twenty such exhibits have been prepared under the supervision of the Board of Trustees of Hospitals for Consumptives. This did not prove to be an easy task. Such an exhibit should be cheap, so as to be within the reach of small towns and villages. It should be light, so that it can be easily handled and moved from room to room. It should be compact, so as to require little work in setting it up and taking it down, and, last, the lessons it teaches must be simple and striking. These features I have tried to combine in our school exhibit, with what success remains to be seen. It should be understood that these exhibits are in the nature of an experiment, and that the Board of Trustees will be only too glad to receive criticisms and suggestions as to the makeup of future exhibits. The price of each exhibit is $35. It consists of two large frames about 4×5 feet, which fold together so as to form a strong, compact box. This box or frame can be easily handled by two men, and can be locked and shipped with perfect safety. Each side of the frame contains twenty-four 8×10 inch smaller frames, in which are set pictures or mottoes. The pictures are covered with celluloid instead of glass. There is a row of mottoes along the top, and another row along the bottom, stating simple truths in regard to various questions of health, hygiene, tuberculosis and how to avoid it, etc. There are photographs, plainly labeled, showing various bad tenement conditions, dusty, dangerous trades, sweat shops, good and bad workshops of various kinds; there are pictures of sanatoria, tents, balconies, etc., for home treatment; pictures of outdoor schools, playgrounds, swimming pools and other similar subjects. Any mention of figures or statistics has purposely been omitted. A pamphlet has been prepared, which will be widely distributed, to go with the exhibit, with suggestions as to its demonstration. It is planned, where possible, to have tuberculosis societies buy this exhibit, so that with the money we may prepare others. Already this exhibit has been placed in Boston, Brookline, Cambridge, Canton, Chelsea, Clinton, Fitchburg, Gardner, Holyoke, Pittsfield, Springfield and Worcester.

We hope that before long many other anti-tuberculosis societies will realize the need of getting at the children by some such method as this. I would summarize this subject as follows:

1. There is practically no place in Massachusetts where young children with open pulmonary tuberculosis can be sent and properly cared for.

2. There are not more than one or two open-air schools where the many thousand anemic and run-down "pre-tuberculous" children can get fresh air and sunshine in addition to a knowledge of reading, writing and arithmetic.

3. Although there is sufficient legislation on the subject, there is at present very little instruction given to young children on hygiene, right living and the prevention of tuberculosis and other diseases.

As remedies for this state of affairs, and as an outline for future work of anti-tuberculosis societies, I would suggest the following:

1. Every effort should be made to get the state and local authorities to provide adequate facilities for the care of children with pulmonary tuberculosis. One effective way of doing this is to make application for the admission of all such cases to the state sanatoria. The strongest argument which the board of trustees of the state sanatoria can use before the legislature is a long list of applications from children for whom there is no place,

[1] This institution is no longer a school, but a day camp or hospital for tuberculous children.

nor for whom, with the present appropriation, can a place be provided.

2. Earnest and intelligent co-operation with the local school board to provide an outdoor school or fresh-air room for pre-tuberculous children; if such a school or room is established, the attention of the city legislature and board of health should be called to the good which it does.

3. It should be insisted upon that the terms of the 1908 act, that "tuberculosis and its prevention shall be taught in our public schools," etc., be complied with. This can best be done by means of tuberculosis exhibits prepared along the lines of those now loaned by the state, placed in all the public schools, and demonstrated wherever possible by doctors, nurses or social workers.

I know of no more fundamental or important work for any anti-tuberculosis society to take up than this.

THE THERAPEUTICS OF LIGHT.*

BY HERBERT MC INTOSH, A.M., M.D., BOSTON.

THE pioneer work of Finsen has served to direct attention in recent years to the utility of light therapeutics. Though his labors were chiefly confined to the treatment of lupus, in the control of which he achieved brilliant success, later students have found that light is applicable to the treatment and cure of a wide range of troubles. The purpose of this paper is to indicate, first, why, upon theoretic grounds, it is fair to conclude that light should exert an important effect upon the cure of disease, and, secondly, to indicate in a general way some of the uses to which it may be put.

It is scarcely necessary to say by way of introduction that light is the condition of terrestrial life. Whatever the life principle is, and it is still a profound mystery, it cannot manifest itself except under conditions made possible by light, and in the preparation of the earth as the habitation of man the precedent evolution of the vegetable kingdom by light was essential.

What a mighty force sunlight is, is made manifest when we reflect that by means of evaporation millions of tons of water are daily lifted into the atmosphere to descend as rain, and fill the water courses which in turn will ultimately be called upon, as the coal in our mines — the product of the sun's mighty activity in the carbonaceous period — is consumed, to supply power for industrial and domestic uses.

In like manner the same silent energy in the springtime lifts the sap from the roots into the trunks and branches of trees and into the stems of countless forms of vegetable life; in the aggregate an uncomputed weight of life-bearing fluid.

The influence of sunlight upon protoplasm is illustrated by many chemical phenomena. Thus bilirubin is oxidized into biliverdin by sunlight even when air is excluded and cl_2 unites with C_2cl_4 in sunlight forming C_2cl_6. Chlorine unites with hydrogen in sunlight with explosive violence to form hydrochloric acid.

The fermentative effects of light are very notable. Thus Niepce de Saint Victor and Corvisant found that a 0.1% solution of starch exposed during six or eight hours to the summer sun becomes transformed into sugar, no change occurring in the dark. In like manner glycogen is transformed into sugar more rapidly in the light than in the dark.

Passing now into the vegetable world, we find that under the influence of sunlight there is formed in the phanerogams or green-leaf plants a product which is called chlorophyll, by means of which the plant is enabled to break up the molecule of carbon dioxide and fix carbon in the form of starch into its own structure, thereby supplying an indispensable food for the sustenance of animals as well as material for the construction of dwellings.

This too brief review of the physical and physiological effects of light in nature prepares us to consider what effect it may have upon human life.

ABSORPTION OF LIGHT BY BLOOD.

Freund squeezed a drop of blood from the tip of his finger upon a quartz film, surrounded by a rim of paper 0.17 mm. wide, and covered it with another quartz film. The layer of blood completely filled the space of 0.17 mm. and showed uniformly red. The spectrum was photographed through a glass spectroscope by means of sunlight. The exposure lasted five minutes and produced no effect upon the photographic plate from lines F ½ G in the direction of the ultraviolet.

A second experiment was made upon the web of a live frog's foot in which the blood stream was flowing. The foot was placed in front of the slit of the spectroscope and illuminated by sunlight. The exposure lasted five minutes. Under these circumstances the line H ($\lambda = 3{,}964$ Å) was absorbed. This is very near the edge of the ultraviolet. From this experiment it is clear that blood absorbs light. It is for this reason that Finsen found it necessary in his treatment of lupus to employ compression upon the area treated in order to squeeze out the layer of blood which acted as a screen to the chemical rays.

Finsen's historic experiment with aristo paper placed behind the lobe of his wife's ear and illuminated for five minutes by the concentrated light of an arc lamp established the same fact. Without compression there was no effect upon the paper, but when the ear was compressed between two glass plates until it appeared bloodless, the aristo paper was blackened after an exposure of twenty seconds. From these experiments we may safely infer that blood absorbs light.

Quincke[1] found that hemoglobin gives off its oxygen more quickly in the light than in the dark. Therefore, light increases the oxidation of the tissues.

This action is somewhat analogous to the influence of light upon the molecule of carbon dioxide in the presence of chlorophyll. Here the atom of carbon is dissociated from the bivalent

* A paper read before the Brookline Medical Club, Nov. 9, 1910.

[1] Pflüger's Archives, 1894, vol. lvii, p. 134.

oxygen which is released, while the carbon in the form of cellulose is fixed in the cellular structure.

Fluorescence is the property which some substances have of absorbing higher frequencies and converting them into lower frequencies. Among these substances are blood and serum. These are, therefore, radiant energy transformers.

What is the significance of this fact that blood and serum like chlorophyll are fluorescent? It has been frequently affirmed, and correctly, that the ultraviolet rays have little penetration, and yet it is generally believed that these rays possess the highest virtue in phototherapeutics. It is certain that Finsen attached the greatest value to them in his therapeutic studies. If, now, they have but slight power to penetrate the skin, their value must be limited to very superficial conditions. Here we are met, however, by the fact discovered by Dr. Henry Bence Jones, in 1866, that blood and serum are fluorescent media. By this is meant that they have the property of absorbing light at one rate of vibration, as, for example, ultraviolet, and transforming it into a lower rate. They are, therefore, transformers of radiant energy, and we are justified in assuming that the absorption of the rays of higher refrangibility by the epidermis is not synonymous with their extinction, but rather with their transformation into another rate of light energy.

Having shown, then, that the ultraviolet frequencies which have little power of penetration are absorbed by the blood stream and have the ability to produce fluorescence and thus profoundly affect the chemistry of the tissues, let us turn our attention to the visible chemical frequencies. These include the upper end of the visible spectrum marked by the blue, indigo and violet. Now, it has been frequently proved that these chemical frequencies of the visible spectrum have marked power of penetration.

Thus Gadneff introduced under the skin of cats and dogs small tubes containing silver chloride. After exposure to sunlight the chloride of silver was found to be blackened, while no change occurred with captive animals kept in the dark.

Darbois[2] put a piece of photographic paper between two watch glasses. He then placed the watch glasses in the mouth against the buccal membrane. The light from a Finsen concentrator was then thrown upon the cheek. The photographic paper was blackened after one minute.

Gebhard[3] imbedded his hand in plaster of Paris, leaving only the back exposed, having placed a photographic plate in the palm. The hand was exposed for twenty minutes to the light of an electric arc lamp. The plate was afterwards developed and showed blackening with outlines of hand and fingers.

Solucha[4] placed strips of silver bromide gelatine under the skin of dogs and sewed up the wounds. The light from a ten to twenty-ampere lamp at a pressure of from fifty to sixty-five volts was thrown upon the parts with the result that decomposition of the silver bromide occurred in one half a minute.

[1] Traitement du Lupus Vulgaire. Thèse de Paris, 1910, p. 80.
[2] Die Heilkraft des Lichtes. Leipsig, 1898, p. 131.
[4] Quoted by Freund.

When the tubes were placed behind the ear or in the mouth against the check, decomposition soon occurred. When, however, the tubes were placed deep in the gluteal muscles, the light had no effect. When placed behind the forearm or in the closed hand there was no decomposition after fifteen minutes.

When, however, the current was increased to twenty amperes at 110 volts, the sensitized gelatine film was chemically altered when placed on the back of the neck or on the side of the body, the rays being thrown perpendicularly upon the film through the tissues.

I placed an x-ray film back of a dental skiagraph and put them between two watch glasses in a dark room. They were then introduced into the mouth between the teeth and the cheek. I then had the light of an arc 2,000 candle-power lamp thrown upon my cheek for about ten minutes and secured a very good picture of the dental skiagraph upon the sensitized film. This was obtained from the rays passing through the cheek. We have thus shown that visible chemical frequencies penetrate the body, and that the ultraviolet rays through their ability to excite fluorescence in the serum and blood stream are converted into chemical rays of lower frequencies.

That the luminous frequencies are capable of penetration is evident from the simple diagnostic procedures employed in the different specialties. Thus a 4 candle-power lamp placed in the mouth is capable of illuminating the maxillary antra; placed in the superior anterior angle of the orbit is capable of illuminating the frontal sinus; when introduced into the stomach by means of the gastrodiaphane illuminates the epigastric and surrounding regions; and when carried into the vagina irradiates an area extending up to the umbilicus.

From this brief survey of the field it is clear that all the frequencies penetrate the tissues, not only the red, yellow and orange, but the highly useful chemical frequencies of both the visible and invisible regions.

Which of these radiations are the most useful in therapeutics? Here again we recognize a general agreement as to the value of the heat waves, so that no need exists to emphasize the importance and value of the rays of greater lengths. Both theoretically, however, and practically, their utility is much less than that of the high rates of vibration. It is only as the wave lengths begin to approximate the diameter of the molecule that the most profound effects are discernible. Thus, while in plant life it is the yellow rays that are chiefly concerned in the function of assimilation, breaking up the carbon dioxide molecule, depositing carbon in the cellular structure and releasing oxygen, it is to the chemical rays that all excitomotor phenomena are due. The rays of greater wave length pass through the tissues practically without change except to impart a portion of their heat to the structures upon which they impinge. In like manner a wave upon the surface of the water is not destroyed

by an object of smaller size, but will fold itself around it and pass on unbroken, but if it be near the size of the obstructing object it communicates its vibration to the opposing object and is destroyed. In like manner the shorter vibration of the chemical portions of the spectrum surrender their energy in the tissues upon which they strike and thus produce their beneficial effects.

The absorption of oxygen by the blood under the influence of the chemical rays and the fluorescence of blood and serum under the influence of the more refrangible portion of the spectrum go far toward establishing the proposition that it is to the upper end of the spectrum that we must attribute the peculiar value of light treatment. I desire to emphasize this point because it is frequently affirmed by those who have given little consideration to the therapeutic uses of light that the value of light treatment resides in the impartation of heat to the tissues. This is measureably true. With the exception of thermopenetration, which has lately been introduced to the profession and which raises the temperature of the tissues in the path of the high-frequency current from eight to ten degrees, there is no method comparable to light for the production of heat in the tissues. The incandescent bath produces sweating in half the time required by a Turkish bath. This is in spite of the fact that the air in an incandescent bath is but little above the temperature of the body. In a Turkish bath the body is enveloped by a blanket of hot air and the temperature of the body is raised by actual contact with the source of heat. In an incandescent bath the radiant heat and light rays from incandescent bulbs traverse the air without impartation of energy, impinge upon the body, penetrate the tissues and produce physiological changes. The chemical portions of the spectrum undoubtedly produce metabolic effects, though it is usual to regard the incandescent bath as primarily a heat bath. It is in any event a much more agreeable form of heat bath than the Turkish bath, and patients quite invariably prefer the incandescent bath to the ordinary hot air bath.

While, however, it is to chemical rays that the peculiar value of light treatment must be ascribed, for general purposes the whole spectrum of white light is to be preferred. There can be no objection to using, and in most cases there is great value in including, the luminous and heat rays in the treatment of disease. Special indication, however, may call now for the exclusion of the heat rays and now for the exclusion of the ultraviolet rays. For general purposes, however, the full spectrum of white light, such preferably as is furnished by an 2,000 candle-power arc lamp, should be employed, and when only one lamp is used, there can be little doubt that this furnishes the best result. It is not denied, however, that the incandescent lamp of high candle power is a very useful agency for general therapeutic purposes.

Having directed attention to some considerations which should lead us to infer that light should *a priori* exert a favorable influence upon disturbed bodily conditions, let us sum up briefly some of the physiological effects of light which have been experimentally proved.

It is a matter of common observation that the skin may become irritated under the influence of the sun's rays and sustain burns under continued exposure which may produce great discomfort. Thus solar erythema and snow blindness are illustrations of the irritant effects of the ultraviolet rays of the sun.

Similarly, the tanning of the skin in summer time testifies to the influence which the sun's rays exert upon the pigment-producing cells of the *rete mucosum*.

Sweating occurs much more rapidly in an incandescent bath cabinet than in a Turkish bath, yet the temperature in the latter is much higher. Light, therefore, has a marked influence upon the sweat glands.

The effect of the impingement of light rays upon the body is to increase superficial hyperemia, and as a determination of blood to the surface cannot take place without its withdrawal from the interior, it follows that when large areas of the body are exposed to light energy there must be a depletion of the viscera.

Light energy is destructive of bacterial life outside the body. Since, however, this destructive action is due chiefly to the ultraviolet rays, and these are not highly penetrative, we are not permitted to affirm a directly bactericidal action in living tissue. I have already pointed out, however, that blood absorbs light, that the tissues fluoresce under the influence of light, and that the hemoglobin gives up its oxygen to the tissues more readily under light exposure. Herein may be perceived the damaging effect of light upon bacteria in the tissues. For as they are anaerobic, the production of oxygen is unfavorable to their growth and the increased activity of tissue combustion produced by light renders the nutrient media in which they live less favorable to their propagation.

The increased absorption of oxygen by the blood under the influence of light leads to increased activity in tissue destruction, and, therefore, augments the elimination of CO_2. In confirmation of this proposition Molschott,[5] Selmi and Piacentini[6] have shown that dogs, hens, pigeons and frogs eliminate less carbon dioxide in the dark than in the light.

In like manner S. Goodnow has shown that human beings and animals secrete more urine, urea and chlorides when continually exposed to daylight than when remaining in the dark. We may thus fairly conclude that light energy increases urinary elimination.

When the nude body is exposed to light energy there is a rise in temperature and an acceleration of both pulse and respiration. These observations of Goodnow have been repeatedly confirmed by the writer. Thus in a recent case treated in the incandescent bath for obesity, the temperature quickly rose from normal to 101°, and the pulse from 80 to occasionally 140. We may conse-

[5] Wien. Med. Wochenschr., 1885, no. 43.
[6] Rend. Conti. del Reale Instituto, 1870, vol. iii, Ser. ii, p. 51.

questly affirm that light tends to raise the normal temperature and accelerate the pulse-rate. It should be remarked, however, that these results are obtained from the whole spectrum, colored rays tending to lower the pulse, particularly the violet.

Sudden exposure to bright light may produce violent sneezing. This is a reflex from the sensory fibers of the trigeminus distributed to the Schneiderian membrane. Hence we may conclude that light energy may produce motor excitation.

Light markedly increases the number of red blood cells. This has been repeatedly demonstrated after an incandescent bath. It also increases the amount of hemoglobin. Under the influence of light oxyhemoglobin more readily surrenders its oxygen to the tissues, thereby stimulating combustion of the tissues. We have already shown that the solid constituents of the urine are increased, that sweating is promoted and that the elimination of CO_2 is augmented.

Cretinism occurs in the dark valleys where the rays of the sun never penetrate, and amenorrhea afflicts the Eskimo women during the long Arctic night. It is very evident, then, that sunlight promotes metabolism.

It would be profitable to spend some time, if it were at my disposal, upon the interesting subject of blue light. Many of you will recall the interest excited among the laity, in the 70's of the last century, by the publication of two books upon the use of colored lights. The first, published in 1876 by Gen. A. J. Pleasonton, of Philadelphia, a veteran of the Civil War, is entitled "The Influence of the Blue Ray of the Sunlight." The other is entitled "Blue and Red Light, or Light and its Rays as Medicine." It was written by a physician, Dr. S. Pancoast, of Philadelphia, and published the following year. These books have for us to-day simply an antiquarian interest. The first is highly fantastic, and neither has much scientific value. They excited, however, a great deal of interest, and all over the country houses were supplied with colored lights; generally blue or violet, sometimes alternate red and blue. On Beacon Street opposite the Common you may still see several stately dwellings ornamented by colored lights which are a memorial of the interest excited by these early writers. These books are now out of print, but may be found in the Boston Public Library.

The fact remains, however, that there is a therapeutic value attached to the blue and the red ray. Thus it is undeniable that the blue ray exerts a constringing effect upon the blood vessels and a soothing influence upon the peripheral nerves, and there is now a general agreement that the blue light is analgesic and in some instances anesthetic, and much clinical proof can be furnished to sustain this proposition. For the relief of superficial neuralgias, as, for example, trigeminal neuralgia, the results are sometimes very astonishing. Myalgia and arthritis similarly often yield promptly to the blue ray. Von Jaksch [7] dwells upon the soothing effect of blue light and uses blue chimneys upon his lamps in his sick wards. The healing of wounds is promoted by the blue light, and Pansini has shown by an elaborate study fortified by ergograms that blue light increases the power to do muscular work.

The efficacy of red light in smallpox depends upon the exclusion of the blue ray rather than upon any virtue residing in the red ray. The chemical ray promotes suppuration. If, therefore, the blue ray is excluded, pitting is prevented and the comfort of the patient promoted by the admission of red light. The use of the red ray in smallpox is associated with the name of Finsen, who was an enthusiastic advocate of this method of managing variola. He was not, however, the first to employ red light in this disease. John, of Gaddesden,[8] who died in 1361, was the author of the first medical treatise in the English language. The son of King Edward I, who was afflicted with smallpox, was under his care. He was placed in a bed with scarlet hangings and red blankets and counterpane. His throat was gargled with mulberry wine and his mouth washed with the juice of red pomegranates. The royal patient recovered without the usual disfigurements attending this dread disease. In Queen Elizabeth's time the value of red curtains and red glass was strongly affirmed by certain physicians, who, however, were regarded by the orthodox physicians of the day as charlatans.

Finsen, while reading in the library at Copenhagen, ran across an account of some sailors, suffering from smallpox, who were confined in a darkened room at New Orleans and recovered without pitting, and was thus led to recommend the exclusion of the chemical rays in the treatment of this disease. Finsen [9] condemns unsparingly the treatment of smallpox cases without the exclusion of the chemical frequencies of light.

Apart from these obvious uses of colored lights, there is undoubtedly a psychical aspect to the problem. Blue is a so-called "quiet color." It is associated with the quiet of the evening, the calm of the twilight and is the symbol of peace. Red, on the other hand, is a so-called "loud color" and is associated with the activity and bustle of the day and is the symbol of conflict and passion. The bull is maddened by it; unchaste women select it as the emblem of their unhallowed traffic, and the ancient temples of Venus were richly adorned with it.

More or less study of the effects of colored lights upon insane patients has been made, somewhat confirmatory of the conclusions already noted. Maniacal patients have, in some instances, been quieted by blue lights, while those afflicted with melancholia have been to some extent relieved by red. At the present stage of experimentation it would not be safe to affirm either uniform or positive results. In some instances they have been negative, as in the experiments of Von Paquet of Moscow.

The value of sunlight in surgery is well illustrated in a paper read at the Second International

[7] xx. Congress für Innere Medizin, 1902.

[8] Phila. Med. Jour., Dec. 7, 1901.

[9] Brit. Med. Jour., June 6, 1903.

Congress for Physiotherapy at Rome, Oct. 13–16, 1908, by Dr. Oskar Bernhard Moritz.[10] The remarkable results which this surgeon has attained in the healing of wounds, ulcers and skin affections he attributes (*a*) to the increased proportion of ultraviolet rays contained in the sunlight of elevated regions. Thus Oberengadin in the Alps, where the results reported were secured, is 1,800 meters above the sea. Here the weakening of the sun's rays through filtration through the atmosphere is enormously decreased and the ultraviolet rays possess greatly increased power. It is to this circumstance that Dr. Moritz attributes the freedom of the mountaineers of the high Alps from lupus and skin cancer, affirming that a chronic solare eczema renders the skin resistant to the invasion of bacteria. (*b*) To the remarkable dryness of the atmosphere in these elevated regions. Here again, however, we have an explanation in the increased ultraviolet content of the sun's rays, since even small quantities of water vapor act as a screen to the passage of the ultraviolet ray; and (*c*) to the absence of bacteria from these elevated regions. A little reflection here will again make clear that the absence of bacteria from mountain air is due to the increased proportion of ultraviolet rays in mountain sunlight.

Dr. Moritz cites the remarkable effect of sunlight upon a wound made in extirpating the spleen, which had broken open on the eighth day after operation, holding only by the peritoneal edges. In spite of curetting and cauterizing it had made no progress in healing. After an hour and a quarter's exposure to sunlight there was a distinct improvement, the granulations were markedly better and stronger and the great gaping wound under this treatment healed quickly. In grafting he simply lays the grafts in the sun upon the dry granulating surface. Within a quarter of an hour it is usually impossible to detach the grafts from the underlying tissue without exerting considerable force.

In like manner drainage becomes unnecessary for the most part in deep wounds, since insolation both dries out the deep pockets and incidentally destroys bacteria. Ulcers and cavities become through insolation in a short time pure and dry. They are quickly covered with a shiny fine parchment-like skin which usually lasts for from twenty to thirty hours, when the wounds are again exposed to sunlight. Any one who desires may readily verify these statements. A wound exposed to sunlight or the electric arc is quickly covered with a parchment-like membrane and the edges are crumpled and drawn together. Frequently no dressing is required.

With equally favorable results Dr. Moritz employs the insolation method in cases of tuberculosis of the skin, glands, joints, bones and larynx.

It is important to observe that in the method of Dr. Moritz, the rays of the sun are not concentrated, neither is there any exclusion of the heat rays, for which he claims under proper conditions both chemical and bactericidal power. In the winter the direct rays of the sun are reinforced by reflection from snow and ice. He reports cases of scrofuloderma which had resisted all other therapy for three years but yielded to sunlight treatment after three months, and two severe cases of lupus, one of which had involved the soft palate and the vocal cords. In cases of bone and joint tuberculosis he combines insolation and immobilization, placing the disabled part in a plaster of Paris jacket and exposing it to the sun's rays through openings cut in the dressing.

Among the other surgical conditions for which sunlight treatment is valuable, he mentions crushing wounds, ulcera cruris, perforating ulcer of the foot, wounds caused by infection, as abscesses, paronychia, furuncle, carbuncle, soft ulcers, buboes, and syphilitic ulcers associated with specific treatment.

It is possible that the very remarkable results obtained at high elevations could not be secured at lower elevations, and that there is a peculiar virtue in sunlight at these high altitudes. It is nevertheless true that sunlight treatment can be employed with advantage in many cases which are carefully excluded from the light by dark dressings, and particularly in those cases which have shown themselves rebellious to ordinary treatment.

It remains for me to state briefly the apparatus required for light treatment. The most generally useful apparatus for office use is in my opinion the arc lamp of 2,000 candle power. This furnishes the whole spectrum, including the ultraviolet rays, upon the importance of which I have sought to lay emphasis in the preceding pages. It furnishes a tremendous volume of rich chemical rays both visible and invisible, as well as abundant heat rays. Screens may be used to furnish blue or red light.

A substitute for the arc lamp is the high power incandescent lamp. Here, however, the ultraviolet rays are entirely cut off by the inclosing bulbs, and the treatment is necessarily to a large extent a radiant heat treatment. This is, of course, of great value, but manifestly inferior to a treatment which utilizes the whole spectrum as does the arc light.

Next there is the incandescent bath cabinet, a most useful apparatus, in which the nude body of the patient is exposed to the radiance of fifty or more sixteen-candle-power incandescent bulbs. With this apparatus it is necessary to combine certain hydriatic procedures in order to produce a suitable reaction and prepare the patient for exposure to ordinary temperatures.

The arc bath cabinet is also a highly useful apparatus. This is a cabinet six or more feet in length and of suitable width and height. It contains a cot upon which the patient lies nude and exposed to the rays from two powerful arc lamps. It is an artificial sun bath.

For dermatological uses particularly, there are lamps after the pattern of the Lortet et Genoud lamp designed to take the place of Finsen's enormous concentrators. These have quartz

[10] Jahrbuch über Leistungen und Fortschritte auf dem Gebiete der physikalischen Medizin, 1908, p. 77.

windows to permit the escape of the ultraviolet rays so important in most therapeutic treatments. Then there are small lamps with iron or other metal electrodes and quartz windows which are almost exclusively ultraviolet lamps.

Finally, there is the Kromayer mercury vapor lamp in which a current of electricity is passed through volatilized mercury, producing a peculiar greenish-blue light. This is provided with quartz windows for the egress of the ultraviolet rays. It has been used chiefly abroad for therapeutic purposes and has recently been adapted to the sterilization of potable water. It is attached to the water faucet and automatically and absolutely destroys all bacteria, rendering water thus irradiated safe for domestic purposes.

Summary. In this brief sketch of the therapeutic uses of light, I have endeavored to show

(*a*) That light penetrates the tissues.

(*b*) That in so doing the chemical rays produce fluorescence of the blood and serum which is reduced or absent in pathological states, as, for example, in malaria.

(*c*) That the action of light upon the blood stream reduces oxyhemoglobin and thus stimulates the chemistry of the tissues, that is to say, improves metabolism.

(*d*) That the most useful portion of the spectrum is not the heat or luminous portion, but the chemical portion.

(*e*) That the physiological effects of light flow easily from the marked penetration of the light rays, particularly the chemical portion of the spectrum.

(*f*) That the blue light has a peculiar field in the control which it has over pain and hyperemia.

(*g*) That red light by its exclusion of the chemical rays plays an important rôle in the treatment of smallpox.

Finally, I have given some illustrations of the efficient action of light, of artificial sunlight, and concluded with a brief description of the apparatus employed in light therapy.

My aim has been principally to show that the use of light for therapeutic purposes is rational and that it is a most important addition to the physician's equipment for the management of disease.

EXTRAPERITONEAL CÆSAREAN SECTION.

BY JAMES LINCOLN HUNTINGTON, M.D., BOSTON.

To realize why this operation was revived and why it was received with such enthusiasm in Germany, one must first bear in mind the condition of German obstetrics. Normal labor is there conducted almost entirely by midwives, who are required by law to call in the obstetrician when complications arise. This results in what we might call ultra-conservative obstetrics — cases come late to operation. The midwives, in spite of their thorough training in the schools under the supervision of the government, and their rigid examinations, are far from being keen diagnosticians or careful practitioners. The number of fatal cases of puerperal fever in Germany annually is still over five thousand. The first indication for operative interference taught the German student in obstetrics is fever during labor (a condition very rarely met with here in America). This is the commonest complication for which the obstetrician answers the cry for help from the German midwife; he comes and finds all too often on examination a contracted pelvis, os fully dilated, membranes ruptured and head above the pelvis brim. What is to be done? The answer was, and still is, in most German Kliniks, craniotomy. Yes, craniotomy on the living child has been far more common in Germany than here in America, and it is because of the frequency of infection during labor for which the midwife is the most constant contributing factor.

But if any one has done this operation, or even seen it executed, he will understand with what feverish ardor the obstetricians in Germany sought for a solution which would save them from performing this hideous operation. The operation of widening the pelvis was looked upon with favor for these cases until the fatalities following even the smallest wound in the vagina — and sometimes apparently without this break in technic — forced the obstetricians to regard infection as the strictest indication against this operation. Then the indefatigable researches into the realm of surgical possibilities revived this forgotten operation of entering the gravid uterus through a wound shut off from the peritoneal cavity.

Before deciding whether or not this operation has solved the problem they were facing, let us review the history of this surgical procedure.

In 1807 Jörg, viewing the high mortality of Cæsareans in the days before antiseptics, conceived the idea of a modified Cæsarean section by opening the vagina and cervix through a low lateral abdominal incision. Acting on his suggestion Ritgen modified this by not opening the vagina, but pushing the bladder to one side and opening the uterus extraperitoneally. In 1821 we have the account of his first attempt at such an operation — an attempt merely, because of uncontrollable bleeding which caused him to change the operation to the classical Cæsarean to save the child's life. The patient died two days later from hemorrhage.

In 1822 Physick, of Philadelphia, in a letter to Dr. Horner, proposed a similar operation, only that he used a transverse incision above the symphysis pubis instead of the median longitudinal incision which Ritgen employed. Again in France in 1823 we have an account of a similar attempt at an extraperitoneal Cæsarean changed during the operation to the classical because of difficulties.

In 1870 Dr. T. G. Thomas, of the College of Physicians and Surgeons in New York, ignorant of previous work along this line, conceived the idea of an extraperitoneal operation and performed such an operation on the cadaver of a young woman who died at term. He found the operation so simple that he resolved to employ it upon the next favorable opportunity. Shortly after this

he did perform the operation on a patient practically moribund with pneumonia. The object in this case was merely to save the child. He delivered a premature infant that expired an hour later. One of his colleagues, Dr. Skene, of Brooklyn, was much interested in the operation and on Oct. 29, 1875, performed the first successful extraperitoneal Cæsarean section on a primipara long in labor with a much contracted pelvis. The incision was made from the pubis to the right anterior superior spine sweeping upwards above Poupart's ligament. Peritoneum lifted up, exposing the junction of the vagina and cervix. An incision was made at this junction and the child delivered through the wound fifteen minutes after making the skin incision. The baby lived, and although the bladder was opened during the operation, the patient made a good recovery and was successfully operated upon for vesico-vaginal fistula one month later.

Other operations followed and Thomas reports cases with four living babies and a maternal mortality of 40%. In 1892 we have the same author discarding the operation in favor of the classical Cæsarean with aseptic technic.

Dr. Whiteside Hime, in Sheffield, England, was the first European to adopt this new precedure in July, 1878, — the baby lived but the mother died.

Dr. Edis, in London, the same year attempted the operation, but again the mother died.

In 1881 Fritz Frank, realizing the danger of peritonitis following migration of infection from the uterus into the peritoneal cavity, performed a Cæsarean with the incision low down in the anterior wall of the uterus and covered his wound in the uterus by building a tentlike fold connecting the broad ligaments and the parietal peritoneum.

Now we pass from the historical to the present, for the following operations, with but little modification, are in vogue to-day and all have their adherents.

Fritz Frank continued at work on the problem even after aseptic surgery had made the classical Cæsarean so safe an operation in clean cases. Could not some operation be devised for infected cases or for cases so long in labor that the danger of infection made the classical Cæsarean out of the question? On Jan. 14, 1906, he performed the following operation:

Trendelenburg position, abdominal incision transversely two fingers above the symphysis, 12 cm. in length; a like incision was made through muscle and parietal peritoneum. The bladder was now drawn forward exposing the lower portion of the visceral peritoneum covering the anterior surface of the uterus; this was also incised transversely for a like distance. Taking the upper margin of this cut in the visceral peritoneum, it was now freed from the uterus and directed upwards, exposing the lower uterine segment. This flap of visceral peritoneum was now united to the upper margin of the parietal peritoneum with a row of interrupted sutures. This left the bladder entirely separated from the peritoneal sac, and that organ was then pushed downwards exposing the lower uterine segment much thinned out. This was incised by a tranverse incision 8 cm. in length. The uterus was emptied, the child was alive and easily delivered through the incision. Uterus and abdominal wall closed in layers to wick, which was placed to drain the uterus. This wick was removed on the fourth day, after which the convalescence was uneventful.

In reporting a series of seven cases, Frank claimed that this operation was superior to the classical Cæsarean because it was less bloody for the following reasons: the distribution of blood to the uterus is mainly to the body of the uterus and to the sides of the cervix; the lower uterine segment has a very poor blood supply. Also the placenta, except in abnormal cases, is situated above the lower uterine segment and so the incision does not enter the placental site, which is a very common minor complication of the classical Cæsarean. He also claims that the danger of adhesions between the intestines and uterus is obviated. Finally, that with drainage the operation is applicable to infected cases.

This operation was the first to receive widespread acceptance, and with this came criticism which has continued to the present day. Cases died of peritonitis, and many authorities claimed that this method did not offer any great protection to the peritoneal cavity. Sellheim presented an operation similar to this in 1908 with the change of a vertical median incision both in the abdomen and the uterus instead of the transverse; this he advised for clean cases only. For infected cases he advised a permanent uterine fistula which would heal by granulation.

Meanwhile a pure extraperitoneal operation was devised by Latzko in contra-distinction to this transperitoneal operation. His technic is as follows: For clean cases he finds no advantage in either the transverse suprasymphysial or the median incision. In cases where there is a fair chance of infection, he prefers the median incision as safer. He advised filling the bladder with 150-200 ccm. of fluid before beginning the operation. He advocates pushing the bladder from the left towards the median line, as Martin has pointed out that at the end of pregnancy the bladder is pushed somewhat to the right, so that the left border of the bladder is approximately in the median abdominal line. In pushing the bladder off from the cervix very little bleeding is met with; a single hemostat is all that he has ever found necessary. The bladder and the right rectus are drawn to the right by a flat retractor. The thin drawn-out lower uterine segment and cervix are now exposed. A median incision is made in the cervix extending just through the boundary of the lower uterine segment. By this method one does not have to worry about the ureters and the large vessels.

After delivery of the child it is well to wait for at least one uterine contraction before beginning to repair in order that the parts may assume a little more normal relationship. In all clean cases he advises complete repair of all the tissues, sewing the abdomen up tight, but in infected cases he

advises putting a wick to the angle of the retrovesical space. Latzko was able to perform this operation to the delivery of the child in nine minutes, — consuming twenty minutes for the entire operation.

This operation seemed to have solved the problem. But as the number of operations on infected cases increased, the mortality rose. The technic is so difficult that often the peritoneum will be opened or so badly bruised that it loses the ability to longer resist bacterial invasion. Then, too, the bladder is often opened. Latzko still firmly maintains that infection of this region is not so likely to occur as is peritonitis when the peritoneum is opened, because of the greater resistence of these tissues. Also, that when infection does occur, it is not such an alarming complication as is peritonitis. But many disagree with him. Bumm, who three years ago considered that this operation had absolutely supplanted the classical Cæsarean, stated last March to the Obstetrical Society of Berlin that this operation, while he personally preferred it, had very little to offer over the classical method. He felt assured that this operation should only be employed in clean cases.

Walthard, in Frankfort, finds no advantage in the extraperitoneal Cæsarean section. He prefers entering the lower uterine segment because of the advantages this has to offer, but he makes no attempt to perform an extraperitoneal operation, feeling assured that sepsis in the retrovesical space is not only as likely to occur as peritonitis, but is as dangerous. He advises craniotomy in infected cases.

Döderlein uses practically the same technic as that of Latzko, but he considers the operation only indicated in clean cases where pubiotomy is contra-indicated, namely, in cases where there is great rigidity of the soft parts, as in most primiparæ, or where the pelvis is too small.

Hofmeier points out that in many of these cases the amniotic fluid has entirely escaped for a long time and the uterus has shut down on the child so firmly that all attempts at delivery are difficult and forceps or version through the abdominal wound often have to be resorted to. He also points out that in cases where a rapid delivery is imperative to save the child's life, the classical Cæsarean is the operation of choice, because no other method offers such a quick emptying of the uterus.

Küstner advises the transperitoneal operation in those cases where the membranes have not been ruptured, and the pure extraperitoneal section for those cases where the membranes have long been ruptured and the danger of infection is considerable. He has also designed a special pair of forceps for delivering the head through the abdominal incision.

Hartman states that in cases where the head is pushed firmly into the pelvic inlet and the membranes ruptured, his operation of choice is pubiotomy instead of extraperitoneal Cæsarean because of the difficulty in delivering the child through the abdominal wound.

But many critics have said that this operation of extraperitoneal Cæsarean section was fraught with great danger of rupture of the lower uterine segment in subsequent pregnancies. Their reasons for this have been on theoretical grounds because of the tendency of the lower uterine segment to rupture spontaneously. However, all observers state that such is not their experience. Lichtenstein reports a second extraperitoneal operation which showed absolutely no thinning of the lower uterine segment in the line of scar, and a second case that delivered herself of twins after forty hours twenty minutes in labor, having had with her previous pregnancy an extraperitoneal Cæsarean. Rubeska reports a case where on the second operation the scar in the lower uterine segment could not be discovered.

The advantages of these operations seem to be, first, that labor can be allowed to go on normally to see if the head will mold into the pelvis, and, when it fails so to do, to have a comparatively safe operation to fall back upon. Added to this are other considerations. The peritoneal cavity remains entirely out of the operation; blood, amniotic fluid and uterine secretions are all excluded. There is no danger of adhesions between the intestines and uterus or abdominal wall. There is less likelihood of hernia in scar. The placenta can be freed in the normal manner and be delivered in the physiological way. The lower uterine segment, because of its thin walls, can be much more quickly repaired. There is less likelihood of hemorrhage. Added to this in infected cases there is a questionable possibility of draining and obtaining a satisfactoty result. On the other hand, there is the difficulty of technic, which is made much more difficult, sometimes impossible, if labor has not progressed far enough to thin out the lower uterine segment.

This was the situation when Dührssen and Solms brought forward their new operation, which they claim has forever solved the question of craniotomy on the living child. Their claim for the operation was that it supplanted absolutely the premature induction of labor, the classical Cæsarean section, hebeostomy, perforation of the living child, prophylactic version and high forceps.

Their first operation was performed Dec. 22, 1908, with the following technic: at the beginning of labor a metreurynter was placed in the uterus and filled with 300 ccm. of fluid. An incision was made from the median line to the left anterior superior spine through skin, muscle and fascia. The blunt dissection of freeing the bladder from the uterus was very easy because the plica-vesico-uterina is but lightly attached at the sides, more firmly in the median line. This dissection was accomplished with very little bleeding. The lower uterine segment was now exposed; an incision was made a little to the left of the median line practically large enough to deliver the head of the child. But to make the operation of extraction easier, the metreurynter was now drawn down and the regular vaginal Cæsarean performed from below, so that the incision in the cervix joined the incision in the lower uterine segment. The

metreurynter was now removed and the child easily delivered above the pelvic brim by means of forceps through the abdominal wound. In clean cases the tissues are accurately repaired; in infected or suspicious cases a drain of iodoform gauze is placed in the abdominal wound and the anterior vaginal wall closed merely to the wick, thus draining the wound through the vagina. As yet only a few such operations have been performed and most of these by modifying the technic in so far as the vaginal operation is first performed and then the abdominal.

Liepman, after performing this operation successfully, passes the following judgment: "The Solms flank Cæsarean is, even for one trained in surgical technic, of all Cæsarean attempts the hardest to execute," but he adds the following summary: no other Cæsarean operation is so certainly extraperitoneal. Unlike other Cæsareans, it can be performed early in labor. It offers the best chance for efficient drainage. Here, as in no other method, the third stage of labor can take its normal course without delaying the operator. No other method is so distinctly limited to the lower uterine segment, thus removing practically all danger of rupture of the uterus in subsequent pregnancies. Finally, no other Cæsarean gives such cosmetic results, the scar being less noticeable than one after the operation for the cure of inguinal hernia.

Thus we have many operations aimed to supplant craniotomy as the treatment indicated for the complication of a contracted pelvis and infection during labor. All except the last have, in the opinion of most obstetricians, failed to accomplish their purpose. The last operation has not as yet been given the test of time. But these attempts have not been in vain, for they have given to midwife-stricken Germany a safer operation than the classical Cæsarean for uninfected cases advanced in labor.

It is a question what application we can make of any of these operations. But it would seem as if the experienced obstetrician should make himself familiar with the technic so that in a case of contracted pelvis, moderate in degree, the patient should be allowed the test of labor with the possibility of a successful Cæsarean and a living child should the head fail to enter the superior straight.

Medical Progress.

PROGRESS IN SURGERY.

THORACIC SURGERY.

BY SAMUEL ROBINSON, M.D.

(Concluded from No. 23, p. 877.)

PROGRESS IN THORACIC SURGERY IN HUMAN BEINGS.

At least fifty surgical clinics are now provided with some form of differential pressure apparatus, and not less than two hundred operations have now been recorded. It is perhaps unfortunate, but at the same time readily understood, that many recent thoracic operations have been done with the application of apparatus for lung inflation which were originally undertaken without differential pressure. It is to be hoped that surgeons who have doubted the value of the use of differential pressure will not regard the reports of such cases as intended to advocate the necessity of this method in all thoracic operations. It has been necessary for operators to become familiar with the mechanism and application of such apparatus. There are furthermore certain thoracic procedures which may or may not result in impairment of respiration, and while some operators have been content with having apparatus at hand in case of need, others have employed it throughout the operation, knowing that its effects at least would not be harmful.

Differential pressure is proving to be of value under the following conditions:

1. For reinflation of the lung at the end of any thoracic operation followed by tight closure of the thoracotomy wound, a persistent pneumothorax being regarded as favoring infection and likely to produce respiratory and circulatory disturbances.

2. In operations upon the chest wall in which the pleura may be accidentally or intentionally

opened, the absence of pleural adhesions in such cases favoring the complete collapse of the lung, with possible fatal results.

3. Operations for lesions, such as abscess and gangrene or hemorrhage, to prevent the aspiration of blood or pus to the opposite lung.

4. For hemothorax following stab or bullet wounds of the lung, inflation of the latter facilitating the discovery of such lesions.

5. For all intrathoracic operations in which the absence of adhesions is suspected, a complete collapse of one lung being a fatal occurrence in certain individuals susceptible to a wide open pneumothorax.

6. Resections of the chest wall for tumors in which the surface of the lung is to be utilized to occupy the denuded area.

7. In certain cases of metapneumonic empyema in which after the evacuation of pus it may seem advisable to reinflate the lung and close the wound (Sauerbruch).

8. In thoracic operations in which possible laceration of the mediastinum (esophagus resections) may lead to double pneumothorax, the latter being invariably fatal.

9. In heart suture by the transpleural method to prevent retraction of the heart and pericardium, and to control the heart beat by regulated pressure.

10. In cases where normal respiration is labored by stenosis of the air passages.

11. In cases of lung excision to lower the pressure in the empty pleural space by hyperinflation of the remaining lung tissue.

It may be said that the greatest contribution of differential pressure to progress in thoracic surgery thus far has been that it has provided a means by which the thoracic cavity may be thoroughly explored on either side with almost as little shock to the individual as in exploratory laparotomy. Tiegel and Willy Meyer have thus explored cases of malignant diseases of the esophagus to determine the extent of involvement and adhesions. In those cases in which they have considered the lesions inoperable, with the aid of differential pressure they have obliterated the operative pneumothorax by reinflation of the lung, sutured the wound, and complete recovery from the operation has followed. Lilienthal has explored the thorax under intratracheal insufflation to localize an abscess of the lung.

While it is true that a large proportion of thoracic operations performed in the past could have equally well been done without differential pressure, it must be conceded that, thanks to this new resource to avoid the dangers of pneumothorax, another group of cases hitherto considered inoperable will be and have recently been attempted. The mortality of this new group will undoubtedly be high at the outset because the technic of certain procedures in the thorax has not been developed in the human being. The interest in the use of differential pressure has furthermore developed a renewed enthusiasm for investigation in the thoracic field, and for this reason it is evident that the general technic in certain operations is being improved, although the progress may not be directly attributable to the use of differential pressure.

We may, therefore, review the present status of surgery of different thoracic lesions in turn, whether the progress may or may not be due to the use of apparatus.

1. *Abscess and Gangrene of the Lung.* Inflammatory processes at the periphery of the lung with pleural adhesions and external signs continue to be operated with low mortality, the drainage in such cases being not unlike that of a localized empyema. Certain cases have been reported as fatal due to the aspiration of infectious material following the loss of reflexes under deep anesthesia. The recent developments in the use of non-toxic local anesthetics has encouraged the use of local anesthesia even to the extent of rib-resection for the drainage of pus cavities connecting with the bronchus. The use of positive pressure has demonstrated that, even under deep anesthesia, the secretions are forced peripherally as soon as the abscess is opened; but inasmuch as at this last stage of the operation the aspiration may have already occurred, use of local anesthesia and the maintenance of coughing and expectoration will doubtless be regarded as a preferable method to deep anesthesia even under positive pressure.

There is a small group of cases in which the abscess may be central and lacking localization by auscultation and percussion of physical signs. In exploratory thoracotomy, palpation of the lobes is facilitated by inflation. That portion of the lung found to contain the abscess cavity may be sutured to the chest wall in preparation for a second drainage operation. This technic of walling off a normal pleural cavity before opening the abscess is undoubtedly facilitated by the inflation resulting from the use of pressure.

The methods of Koerte and Lenhartz of excising an abscess cavity and suturing the skin and muscle flap to its base have attracted some attention, but have not as yet been generally accepted.

2. *Bronchiectasis.* The operative treatment of this condition has hitherto been most unsatisfactory. Those cases in which so-called bronchiectatic cavities have been drained by the usual methods have rarely resulted in final cure, and frequently in the establishment of bronchial fistulæ. It is conceivable that some of the more favorable cases known as bronchiectatic abscesses may have been localized lung abscesses not associated with diffuse bronchiectasis and not characterized by the presence of influenza bacilli, which have been found to be omnipresent in true bronchiectasis (W. H. Smith). More frequent have been operations in which one bronchiectatic cavity was drained without improvement of the patient because of the presence of multiple other cavities in the same lobe. The examination of such lung specimens at autopsy indicates that operative removal of the disease is only possible by at least the excision of one lobe to which in certain cases the disease may be confined. The investigators of the use of differential pressure who have learned the successes of lobe excision in animals are now attempting the same procedure

in the human. Willy Meyer has attempted lobe excision in three cases of bronchiectasis under positive pressure without success, although it must be admitted that the frank and detailed description of his operations is a great contribution and does not discourage further attempts. The presence of bronchial secretion during the preliminary anesthesia previous to the ligation of the bronchus and the firm adhesions between the lobe involved and neighboring structures and the poor resistance of such patient to operative procedure were factors which evidently influenced his results. Garré has successfully removed a bronchiectatic lower lobe. He performed rib resection to collapse the chest wall to the root of the bronchus, delivering the lobe extrathoracic and amputating it at a second operation. Kuettner reports two cases of diffuse bronchiectasis in which the lobes involved were freed from adhesions and a portion of the chest wall excised presumably to allow collapse A second operation for drainage was done in one patient whose wound remained unhealed. The other patient could not be traced. Lung excision was not performed in either case. Positive pressure and negative pressure were used respectively. Schmidt, Petersen and Forlanini report the cure of three bronchiectatic cases by the production of artificial pneumothorax with nitrogen injection.

3. *Tumors of the Lung.* The recent revival in accuracy in diagnosis and treatment of lung conditions has led to the conclusion that malignant disease in the lung and pleura is of more common occurrence than previously recognized. It is undoubtedly the least favorable condition for operative attack of all thoracic lesions save perhaps cancer of the esophagus. Two cases are reported by Kuettner, one recognized by sputum examination, the other at time of operation. One case died subsequently of cachexia in which excision is not reported; the other was improved by the removal of a sequestrum in the center of the malignant portion. The ever-present extensive adhesions associated with malignant disease of the lung will always continue to be an obstacle to the only possible surgical treatment, namely, excision.

4. *Empyema.* Patients afflicted with empyema in which the lung has become adherent are not prone to the serious symptoms which may in other conditions follow an operative pneumothorax. There are, however, certain cases of extensive purulent pleurisy immediately following pneumonia in which adhesions have not formed and in which the sudden onset of operative pneumothorax in conjunction with the existing pyothorax may cause some embarrassment of respiration. Such cases are rare, however, and the symptoms may be avoided by plugging the drainage opening at the end of expiration. When such conditions can be anticipated, the use of differential pressure is an additional safeguard. In cases of double empyema both sides may be operated at the same time under differential pressure, provided one chest is closed tight at the end of the operation. The report by Sauerbruch, in 1908, of two cases of acute empyema operated under differential pressure with tight closure of the wound after the evacuation of pus, resulted in recovery, and seemed to promise a new source of prevention of chronic empyema cavities. Willy Meyer has, on the contrary, operated upon three such cases, in two of which "pocketing" occurred and a second drainage operation was necessary. The duration of the disease was somewhat shortened, however. There is reason to believe that if fibrin and lymph clots are removed at the operation and the pleural surfaces treated with antiseptic preparations, it will be safe to re-expand the lung, approximating the pleural layers and hermetically closing the operative wound. Some progress will doubtless be made along these lines.

The antiseptic methods of Murphy and Beck with the injection of glycerine and formaline, or bismuth and vaseline, have undoubtedly contributed to the treatment of empyema. Toxic effects have been noted, but may be avoided with skillful application of the treatment. Certain cases have been reported as cured by the Beck method because the wound had closed. In such cases a cavity may persist which is filled with a sterile non-purulent material from which no toxic absorption occurs, and which is eventually obliterated by the thickening of the pleura and the slow formation of granulation tissue. As the methods of antiseptic injections and the use of differential pressure are improved, a marked diminution in the number of patients with chronic empyema may be looked for. Both positive and negative pressure have been successfully employed in the re-expansion of the lung during the convalescence from empyema operations. Some observers have employed pressure at the end of the drainage operation and attempted to seal the wound without suture with absorbent dressings. Subsequent changes of dressings have likewise been performed under differential pressure, and these observers have believed that the re-expansion of the lung was favored and the convalescence shortened by these procedures. It may be stated, however, that the faithful use of so-called "blow-bottles" should accomplish the same results; and it is doubtful if this repeated application of differential pressure apparatus will continue to be regarded as of particular value.

5. *Tumors of the Chest Wall.* Haecker and Sauerbruch have reported six favorable results from excision of portions of the chest wall with plastic operation of skin and muscle flap upon the exposed lung to cover the defect in the thoracic wall. Resection of chest wall tumors has always been attended with considerable success and will doubtless be attempted with greater persistency when differential pressure is available to maintain lung inflation both during and at the close of the operation. The success of such operations seems to depend largely upon the avoidance of leakage, and it may be said that the use of artificial lung inflation will favor the tight closure of the wound inasmuch as the lung itself can thus be utilized to assist in closing the defect.

6. *Foreign Bodies.* The extraordinary develop-

ments in bronchoscopy made by Bruening, Killian and others have resulted in the successful removal of foreign bodies even in the terminal bronchi, and the necessity of transpleural approach is thereby lessened. Meanwhile, however, the safety of exploratory thoracotomy which is guaranteed by the use of differential pressure justifies the transpleural route with good chances of ultimate success in cases beyond the reach of bronchoscopy.

7. *Oesophagus.* Thirty-seven cases of resection of the esophagus in human beings have been reported with a mortality of 100%, and a large majority of these have been performed under differential pressure. Attempts to approximate the end of the esophagus after resection of a cancerous portion have been even more unsuccessful than in animal experimentation. The common explanation is that this lack of success is due to infection of the pleural cavity which is presumed to occur from leakage in the suture. Schmieden believes that this leakage is favored by the suction present in the pleural cavity, a factor which is not present to disturb the healing of abdominal anastomoses. Injury due to a manipulation of the vagus nerve has contributed to death in certain cases (Kuettner and Meyer). There are doubtless other factors which contribute to failure, among which must be mentioned the resultant excessive tension following excision of any considerable portion of the esophagus. Janeway and Green report a case of resection of the lower esophagus and all but the prepyloric portion of the stomach by their combined thoracic and abdominal approach, with death from empyema despite their repeated successes with this operation in animals. It is agreed by those of the greatest experience in view of the recent failures in anastomoses that resection under double ligature with subsequent gastrostomy is the only justifiable procedure at the present time. It is conceivable that the transplantation of the small intestine from the abdomen to the thorax to occupy the gap in the esophagus may be successfully performed. As reported by Roux and others, the proximal end of the esophagus in the neck may be connected to the gastrostomy wound by a segment of transplanted intestine. It is not inconceivable that a like procedure may be undertaken within the thorax.

8. *Bullet and Stab Wounds of the Heart and Lungs.* It is commonly recognized that many cases of bullet wound of the lung heal spontaneously, and that operative interference has sometimes been more disastrous than beneficial. Statistics of such injuries collected by Kocher show, however, that the mortality of all gunshot wounds of the chest is high. The cause of fatalities is ordinarily either hemorrhage or valvular pneumothorax. Both of these conditions are subject to repair by suture after exploratory thoracotomy, which, as has been stated, is a recognized safe procedure under differential pressure. Before the introduction of this agent, injuries to the lung were sutured, but no attempt was made to reinflate the lung and prevent a persistent pneumothorax, the latter undoubtedly favoring sepsis, as demonstrated by a large series of animal operations. It may be concluded, therefore, that in those cases of lung injury in which the signs of increasing hemothorax are present, operation under differential pressure is indicated, and should lower the present mortality in such cases.

Of 128 reported cases of bullet and stab wounds of the heart, 67 have recovered. It is presumed that all successful cases have been reported, and that many failures have been omitted. Therefore, the percentage of recoveries according to these statistics may be misleading. Furthermore, in view of the fact that spontaneous recovery from heart wounds is not infrequent, it may be argued that certain of these reported cases would have recovered without operation. A large percentage of these cases have been performed without the use of inflation apparatus, although oxygen has frequently been employed by the usual methods. The method of attack has with few exceptions been by the interpleural approach. Every conceivable form of skin, muscle and osseous flap has been suggested, with and without removal of portions of the sternum to expose the pericardium without opening the pleura. A sufficiently high percentage of the recovered cases have been treated without subsequent drainage of the pericardium to persuade us that under aseptic precautions this feature is unnecessary.

Autopsies have repeatedly shown that wounds of the lung are not infrequent in conjunction with those of the heart. Such complications have been found to occur in some of the unsuccessful operated cases where the heart alone was sutured. The observations of Haecker and Sauerbruch are pertinent in this connection. By the transpleural route with intercostal incision and use of rib-spreader under differential pressure, the heart and lung are exposed. Without the use of apparatus, such an approach is not justifiable for three reasons. Upon opening the chest the heart will recede to a point where suture is difficult. The exsanguinated patient with weakened heart is more susceptible to the effects of pneumothorax. Reinflation of the lung and obliteration of pneumothorax are impossible without apparatus, and subsequent impairment of respiration and sepsis are favored. (It should be remembered that the intercostal stitch of Mikulicz has further guaranteed the air-tight closure of thoracotomy wounds, and all other forms of suture are frequently attended with leakage.) Under differential pressure, on the contrary, the inflation of the lung on the unoperated side forces the heart into an approachable position, produces a bubbling of air from the concealed perforations of the lung and, furthermore, facilitates the heart suture by controlling the force and rate of the heart-beat in the method which we have previously described under experimental progress. Brewster has, in a case of bullet wound of the heart, verified the recommendations of Sauerbruch and Haecker, demonstrating the possibility of checking the leakage from the perforated ventricle during suture by manual oc-

clusion of the great vessels at the base of the heart. Both these factors of controlling the pulse-rate by the employment of low differential pressure and diminishing the hemorrhage by direct pressure on the heart vessels are contributed by the transpleural method, and consequently are lacking by the more common direct approach through the anterior mediastinum.

CONCLUSIONS.

Gratification may be obtained then from the untiring efforts of many investigators within the last five years.

The perfection of apparatus for the use of both forms of differential pressure has resulted in its adoption in more than eighty surgical clinics, and it has justified its existence not only by making operable a group of intrathoracic lesions which had previously been abandoned, but has also throughout its required use in experimental observations on the dog contributed to the general technic of intrathoracic surgery.

Reports of Societies.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

THIRTY-SECOND ANNUAL MEETING, HELD IN WASHINGTON, D. C., MAY 3, 4, 5, 1910.

JAMES E. LOGAN, M.D., *President.*
JAMES E. NEWCOMB, *Secretary.*

(Continued from No. 23, p. 880.)

VII. THE INFLUENCE OF THE USE OF THE AUTOMOBILE UPON THE UPPER AIR PASSAGES.

By DR. D. BRYSON DELAVAN, New York.

The wide introduction of the motor vehicle makes it a matter of great human interest as well as economic importance to study its effects upon the physical welfare of the public. Little or nothing has been advanced with regard to its effects upon the upper air passages. The factors which work injury to the air passages may be divided into two groups: (1) Conditions relating to the air itself — temperature, air currents, air pressure; (2) impurities carried by the air — smoke, dust, emanations from plants, and small insects. Under conditions similar to those met with in some forms of automobile riding, as in walking in the face of a blizzard, great harm has been done to the air passages. Dust may be irritating from its mechanical properties as well as from the peculiarities of its nature, and the smoke of the automobile is undoubtedly capable of causing severe irritation to the upper air passages, even in healthy individuals. Where the membranes are already sensitive, as in patients suffering from asthma, bronchitis, tuberculosis, etc., the irritation is all the greater. Mucous membranes already irritated are especially liable to infections of a general nature. Theoretically, therefore, the use of the automobile should increase respiratory ills; whether this has actually resulted is a question.

In using the automobile prudence as to dress, and care should be observed. Chauffeurs might be supposed to suffer more than others, but as a matter of fact, they do not seem to suffer more from throat and lung troubles than others — probably on account of their youth and vigor, and because of the health-giving effects of life in the open air. Certain life insurance companies which formerly made an extra charge against chauffeurs have removed this and now accept them at the usual rate, having apparently found that they are not more liable to life-threatening respiratory diseases than are coachmen. Less serious affections are not noticed in the insurance statistics. Auto riding should be interdicted in acute coryza. Where tendency to involvement of the nasal sinuses exists, automobile riding offers many elements of danger. In chronic sinusitis and old suppurative conditions of the ear, incautious motoring is liable to be injurious. In patients suffering from tinnitus, motoring is often found to be objectionable, and it would seem to be contra-indicated in acute catarrhal conditions. On the other hand, in many subacute and chronic catarrh conditions it seems to be advantageous, and several cases of asthma have been reported as benefited. Prof. James Tyson has maintained that many cases of cardiac disease are markedly benefited by motoring, the fresh air, mild exercise, gentle stimulation of the circulation and mental diversion having an excellent influence; so, in properly selected cases of respiratory troubles, the patients thrive, owing to improved oxygenation and nutrition. It would finally appear that under certain conditions and in certain cases the motorist may expose himself to positive risks unless he exercise proper precaution in the selection of a machine, and wisdom in using it. Properly used, in suitable cases, the automobile may be a valuable therapeutic agent. These things being true, we should by this time have obtained sufficient knowledge to enable us to warn the public of the possibilities of danger and instruct them as to the best means of precaution. In addition to the precautions of a personal nature which those using automobiles should observe, the safety and comfort of the public would be greatly enhanced: (1) By good and well-kept roads; (2) by well-paved city streets kept free from the fine dust which is now allowed to remain after the coarser matters have been removed; (3) by the enforcement of the laws against automobile smoke in our cities, as such laws are enforced in Europe.

DR. E. L. SHURLEY, Detroit, said that living in a city where 60% of all the automobiles manufactured in the world are found, a number of observations have been made by him where the automobile was the etiological factor in the development of conditions in the respiratory tract. An absolutely new occupation has developed within the last few years, that of automobile tester. These men are subjected to the ill-effects of the exhaust pipes for a number of hours each day, and many of them have developed deflections and pathological conditions requiring interference which have not appeared in those following other occupations. The use of the automobile predisposes to the extension of acute conditions that are present, especially the open machine. He has seen a number of cases of wind paralysis with attending ear and throat complications in which the automobile was the particular etiological factor. Another point that develops from the high speed these testers employ is the "automobile face," with the open mouth, and such individuals are subjected to extra dangers of infection.

DR. JOHN O. ROE said that the automobile shield has done more to lessen the dangers from automobiling than any other device, especially cases of frontal sinus disease, induced by air pressure and strong currents, which are less frequent since the adoption of the shield.

DR. WILLIAM KELLY SIMPSON, New York, said that he would like some member to cite definite cases which were dependent upon the automobile.

DR. ROE replied that before the adoption of the wind shield he had a number of frontal sinus cases which were directly traceable to taking cold from the strong

currents to which the patients were exposed. In reply to a query from Dr. Cohen as to whether he attributed this to the excessive speed employed, he answered in the affirmative.

Dr. Emil Mayer, New York, said that, at a former meeting in Boston, he had reported a number of cases of accessory sinus disease in patients who had used the machine, and had called attention to the automobile as an etiological factor.

Dr. Casselberry, Chicago, said that there was a vagueness in such statements that does not carry conviction. So many people use the automobile nowadays that it would be a very uncertain factor.

Dr. Delavan, closing the discussion, apologized for bringing such a semi-popular paper before the Association, but said that the automobile is capable of doing much harm as well as good. The conditions which interdict its use are not always easy of recognition, and the question should be studied, so that its use may be recommended or discouraged, as the case may be.

VIII. INTRANASAL ROUTE FOR GROWTHS OF THE HYPOPHYSIS WITHOUT EXTERNAL INCISION, WITH REPORT OF A CASE OF INTRANASAL COMPRESSION.

Dr. Norval H. Pierce, Chicago.

Dr. John Mackenzie, Baltimore, said that his assistant, Dr. West, has been interested in this question for the past year, and had worked out the method on the cadaver in a very clear and practical way, though they had not yet so treated a clinical case. Dr. West was the first to carry out on the cadaver the operation on the hypophysis from the intranasal route, and has published his results in the *Journal of American Medicine*.

Dr. R. G. Myles, New York, said that he had had three cases where the tumor involved the sphenoid, in which it was necessary to remove the septum, and he had been much impressed with the broad field thus obtained for operative procedure.

Dr. T. Gordon Wilson, Chicago, said that Dr. Pierce had reported the subject of this paper before the Chicago Medical Society last year.

Dr. Pierce, closing the discussion, said that he had outlined the operation in November of last year and had sent the paper to the publisher, though through delay on the part of the printer it has not yet appeared. He understood that a man in Vienna had outlined the operation at the International Congress of Budapest. He himself was not contending for the question of priority, but merely wished to present this new subject.

IX. DIFFERENTIAL DIAGNOSIS OF DENTIGEROUS CYSTS OF MAXILLARY ANTRUM.

Norval H. Pierce, Chicago.

Dr. W. E. Casselberry, Chicago, said that he had been much interested in the paper and the beautiful slides shown by Dr. Pierce, hoping to have clarified a point of diagnosis upon which he had written several years ago, under the title, "Serous Diseases of the Maxillary Sinus." The condition, however, is not yet clear to him. The point for diagnosis is not of cases where there is bulging, but where there is no bulging; as to whether the straw-colored fluid is or is not cystic, whether it is not a primary stage which will become suppurative.

Dr. Cornelius G. Coakley, New York, said that in the early diagnosis of these cases, the precystic state, transillumination does not help a particle. The only way they have been able to diagnose such cases is by having a special x-ray plate with the negative plate placed inside the mouth, in order to get at the floor of the antrum. The information given by such a plate, where there is disease, is absolutely characteristic.

Dr. Pierce, closing the discussion, said that he had not considered the follicular variety of dentigerous cyst in his paper at all. As to the variety spoken of by Dr. Casselberry, the hydrops, the point is whether there is hydrops. When the antrum begins to bulge it is not due to the hydrops *ex vacuo*, but to the dentigerous cyst. He had written a paper describing a case in which a dentist had pulled a tooth, the extraction being followed by a grayish fluid. The patient came to him and he readily washed out the antrum through the antral opening, and the diagnosis was complete. Operation showed a membranous cyst which extended over the cavity.

PRESENTATION OF INSTRUMENTS FOR DIRECT INTUBATION.

By Dr. H. P. Mosher, Boston.

Dr. John R. Winslow, Baltimore, said that since reading his paper before the Association last year in Boston recording a case of chronic stenosis of the larynx treated by intubation by the direct method, he has treated several other cases in the same way. The method possesses great accuracy and exactitude. Dr. Mosher has improved and enlarged our armamentarium by the method described, which will be of great advantage in cases of chronic stenosis.

Dr. W. K. Simpson, New York, said that he had been much impressed with the presentation of the instrument, and had been glad to hear Dr. Winslow's remarks, for he had been wondering what was the advantage of the direct over the indirect method of intubation. He felt, however, that the same accuracy claimed by Dr. Winslow could be obtained with indirect intubation, for the sense of feeling and touch is very accurate, and in the great majority of cases it is better to operate with the head mirror. He is also inclined to think you can get more pressure by the indirect method. He wished to know if any one had had any experience with this method in children. The time required might be an objection to it.

Dr. Clark, Boston, said that he had used Dr. Mosher's instrument in a case of stenosis of the larynx in a child, and found it very useful in introducing and removing the tube.

Dr. Algernon Coolidge, Boston, said that without discussing the question of the kind of case in which it was the better method, it would seem that one was working less in the dark than when doing it indirectly.

TECHNIC OF A RADICAL OPERATION UPON THE MAXILLARY SINUS.

Presented by Dr. William L. Ballenger.

1. Incision under infiltration and cocaine anesthesia in the vestibule of the nares along the ridge formed by the naso-antral angle.

2. The periosteum over the anterior wall of the antrum was then elevated.

3. The naso-antral angle was then removed with rongeur forceps until the anterior angle of the antral space was opened on a level with the inferior meatus.

4. The entire naso-antral wall beneath the attachment of the inferior turbinal was removed through the opening at the anterior angle with Wagner forceps. The heavy portion of the mass at the floor of the nose was still further removed with a small chisel and mallet, thus making an opening extending from the extreme anterior angle to the posterior extension of the antrum, and from the floor of the nose to the attachment of the inferior turbinal.

The claims made by the author for this operation

were: (*a*) That it is as radical as the Denker operation, since it affords as complete access to the antrum for curettage, treatment and inspection; (*b*) that it is a much more conservative operation, as it does not injure the inferior turbinal, and may be done with much less loss of blood and under local anesthesia in a few minutes of time.

(*To be continued.*)

Book Reviews.

The Sexual Disabilities of Man and their Treatment. By ARTHUR COOPER, Consulting Surgeon to the Westminster General Dispensary; formerly House Surgeon to the Male Lock Hospital, London. Second edition, revised and enlarged. New York: Paul E. Hoeber. 1910.

That Dr. Cooper's book should so soon have reached a second edition is evidence that it has been read and appreciated. Though revised and enlarged, the present volume remains, seemingly, as small and readable as the original. Under general treatment, the section on matrimony seems particularly good, but a trifle short-sighted. In this respect the author might have succeeded better had he taken as his motto the quotation: "Let me not to the marriage of true minds admit impediment."

Cystoscopy as Adjuvant in Surgery. With an Atlas of Cystoscopic Views and Concomitant Text for Physicians and Students. By Staff-Surgeon DR. O. RUMPEL, Lecturer in Surgery at the University of Berlin. Only authorized English translation by P. W. SHEDD, M.D., New York. With 85 illustrations in color on 36 plates and 22 textual figures. New York: Rebman Company.

This book consists of about sixty pages of text followed by 36 colored plates representing cystoscopic pictures of bladder pathology. The text is divided into eight short chapters as follows: Anomalies, Congenital; Calculi; Cystitis; Foreign Bodies; Hypertrophy of the Prostate; Prostate; Tumors; Testing Renal Function. Each of these chapters contains a brief, practical discussion of the conditions under consideration, with constant reference to the plates which picture these conditions; and really the whole text is little more than an explanation of the plates embodied in the book. The text itself is also well and profusely illustrated. The whole book has for its basis a collection of cases in the writer's hospital and private practice, and as these patients nearly all came to operation, the cystoscopic diagnoses could be confirmed in almost every instance by the operation and by the subsequent histological examination. The plates are beautifully reproduced, representing the actual cystoscopic pictures seen in the series of cases referred to. The book is creditably executed, and while not one to appeal to the general medical public, will be of interest and really valuable to the genito-urinary surgeon and to all students of cystoscopy.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, DECEMBER 15, 1910

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 690 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 TREMONT STREET, BOSTON, MASS.

MEDICAL EDUCATION AT HARVARD UNIVERSITY AND ABROAD.

COMPARISONS in educational as in other matters are often useful. It is of particular interest, from time to time, to compare methods of medical instruction as practised abroad with those of the best institutions of this country. In this connection, a painstaking study of conditions as found in various European countries has been made by Prof. L. J. Henderson, of the Harvard Medical School, and a comparison drawn between them and the school in which he is a teacher.

Dr. Henderson found that the Harvard School differs radically in several respects from every institution of medical education in Europe, disregarding Spain, Portugal, Russia, the Balkan States and some others. A striking difference at the outset is the fact that the age qualification for practise in Europe is everywhere lower than at Harvard and institutions of similar standing in this country. As is generally known, the student is permitted in Europe to begin his medical education immediately upon leaving school. The difference, however, in the preparatory schools should be borne in mind before too radical deductions are drawn from this statement. The student in Europe is not required to do work of a non-medical character, with the exception that in some British universities, if he desires an A.B. degree, such work is required in insignificant amounts. Even at Oxford, however, it is very unusual for a student to undertake work of an unnecessary kind unless it be advanced study or research in a natural science. It is, therefore, exceptional in England for students to devote time to outside studies before beginning the practice of medicine. In Europe the rudiments of chemistry, physics and general biology are uni-

versally required as parts of a medical education. Time given to academic exercises is very much greater here than in Europe, nor do students in Europe spend so many hours in laboratories doing class work in the medical sciences. It is also noticeable that the Harvard Medical School is much more given to examinations covering small parts of the curriculum at frequent intervals.

The individuality of the student is far less developed here than in Europe, as shown by the fact that the first three years of the medical course at the Harvard Medical School, for example, is essentially the same for all students, whereas much more liberty is allowed abroad. As Dr. Henderson expresses it, nowhere in Europe, save in England, is there so much "spoon feeding" as there is here, but in England there appears to be more. Dr. Henderson concludes his observations by the general statement that Harvard students work more, study a great deal less and "cut" less than their European *confrères;* and that Harvard students less often than Germans, Austrians, Swiss and Dutchmen undertake work of an unusual character, such as physiological research, advanced courses in pure chemistry and the like.

SOME ASPECTS OF HEREDITY.

Heredity has at all times been a rather alarming, and at some times a terrible, word. In the early days, when it was first given general scientific currency by Darwin and his contemporaries, it acquired a connotation of baneful significance, as if representing a cumulative curse bequeathed from one generation to another. Diseases, deformities and evil tendencies of all sorts were described as hereditary, until most of the laity and many physicians came to think of heredity as a malign Dagon from whose predestined doom none could hope to escape.

Following the demonstration that tuberculosis is not a directly heritable disease, there was somewhat of a reaction from this fatalistic view, and some came even to regarding heredity as of no importance at all. Doubtless the truth lies midway between these attitudes, but at the present time there seems still a tendency to overemphasize the gloomy side of the prospect.

It is probably true that the mental and nervous instability which predispose to insanity are heritable, that susceptibility to cancer, to diabetes, to tuberculous and other infections are heritable. Nevertheless it should be remembered that insusceptibility and immunity, relative or absolute, are probably also heritable, and that there is probably a blessed tendency to the self-eradication of defects. For experiments in breeding show that, on the whole, offspring do not often inherit a defect from one parent. Only when there is the same defect in both does hereditary transmission become the rule. If it were not for this, our poor human race would long since have succumbed to disaster.

Heredity is really our friend; it helps us more than it harms. The newly established science of eugenics may be described as the science of applied heredity, whereby we may hope deliberately to aid and hasten the results that are being blindly but unerringly worked out by time. Medically, heredity should never be used as a bugaboo to scare the timid with horrible prospects of inevitable misfortune. It should be presented not as a demon, but as a kindly, though sometimes stern, guardian. To heredity one generation owes what is good in it; it owes to posterity the transmission of that good augmented by the same agent. Heredity is the silver cord that links the ages of man through his evolution, that leads from the shrine of animalculate existence to perfections as yet unimagined.

CONTINUANCE OF DROUGHT IN MASSACHUSETTS.

In several issues of the Journal this fall we noted the prevalence of drought in Massachusetts, and the imminence of water famine in various towns of the state. This situation was temporarily somewhat relieved by the rainfall of last month, but the advent of freezing weather prevented much of this rain from reaching reservoirs where it could be available for drinking purposes during the winter. The precipitation of the year is now fourteen and one-half inches short of the normal annual average. The towns at present most seriously affected by the deficiency are Salem, Athol, Whitinsville, Palmer, Monson, Montague, Milford, Westboro, Greenfield and Belchertown. In certain places in Maine and New Hampshire also there is shortage of water for bathing and drinking and for watering cattle; and several mills near Manchester, N. H., and at Milford and Stillwater have been obliged to shut down for lack of power. This failure of water-supply throughout New England may perhaps be only a coincidence, or may represent the result of far-reaching causes. It is a situation which demands earnest consideration on the part of publicists as well as of water commissioners and boards of health.

PROSECUTION OF THE ORDINANCE AGAINST SPITTING.

THERE seems a determined intention on the part of the Boston Police Board to enforce rigorously the municipal ordinance against promiscuous public expectoration. During the first seventeen days of the recent special enforcement of this law, 459 persons were arrested for spitting. At first a fine of $2 was usually imposed. Later, as there seemed to be no cessation in the amount of spitting, the fine was increased to $5. One man, arrested for a second offense, was fined $10; and one who refused to pay his fine, though able to do so, was sentenced to eight days in the House of Correction. Of the 459 persons arrested, only 1 was a woman; 283 were men between twenty and forty; only 2 were juveniles; 205 were married and 254 single, though it seems questionable whether this should be taken as corroborative evidence of the supposed disciplinary value of matrimony or of the fact that "single men in barracks don't grow into plaster saints." In any event, persistence in the present laudable campaign seems indicated, for the latest general order from police headquarters concludes as follows:

"All members of the force, and especially division commanders, are to understand that the enforcement of this law is to be thorough and continuous. Signs of its violation in any particular section of the city will be regarded as evidence of inattention to duty on the part of the police responsible therefor."

EPISODES IN THE SUPPRESSION OF THE ILLEGAL SALE AND USE OF DRUGS.

THREE prisoners were arraigned before the Boston Municipal Court last week on the charge of selling drugs illegally. Two sold opium and one cocaine. The cases were all continued, and the defendants held in $500 bail each. Four other men were also arrested in Boston last week on a charge of selling morphine illegally and one for selling opium. In this connection it is interesting to note that in Pittsburg, Pa., a man, arrested because an opium outfit was found in his house, has made the defense that it was solely for his own use and that the police have no authority to interfere with his addiction to the drug.

The decision in this case may prove an important precedent as to the right of an individual to practise the use of a deleterious drug. The once divine right of every man to go to the bad in his own way, provided he harm no one else, has come in question like the anointed authority of kings. The real fact of the issue is that all individual wrong doing, whether moral or hygienic, does harm others, who, therefore, have a right to undertake its inhibition.

MEDICAL NOTES.

A CENTENARIAN. — Mrs. Bridget Mahar, who died last week at Hampton, N. Y., was locally reputed to have been born in 1805. She came from Ireland to the United States as a young girl and had been a resident of Hampton for over sixty years. She is survived by one daughter and one son.

OPENING OF A NEW HOSPITAL IN ST. LOUIS. — It is announced that the new building of the Barnard Free Skin and Cancer Hospital at St. Louis, Mo., has been completed and will be opened for inspection on Tuesday, Dec. 20.

PLAGUE IN MANCHURIA. — It is reported from Harbin that the epidemic of bubonic plague in Manchuria is rapidly spreading and that many physicians are being sent by the government from Siberia to attempt its suppression. Traffic with China has already been restricted and may be suspended in the effort to check extension of the infection.

FIRE MENACES A CANADIAN HOSPITAL. — News from Winnipeg, Canada, states that on account of fire in a neighboring lumber mill, which menaced Stroch's Hospital in that city, 80 patients in the hospital were safely moved to another institution. The thermometer at the time was sixteen degrees below zero.

DEPORTATION OF HINDUS FOR UNCINARIASIS. — It is reported from San Francisco, Cal., that of 15 Hindus who reached that port on Dec. 11 on the steamer *Manchurian*, 11 were found to have uncinariasis and were, therefore, ordered by the local medical inspector to be immediately deported.

TYPHOID FEVER AT ANNAPOLIS. — During the week ending Dec. 10, five more new cases of typhoid fever were reported among students in the United States Naval Academy at Annapolis, Md., making a total of twenty-nine cadets now ill with the disease. There have as yet been no fatalities. It is believed that these new cases are derived from the original source of infection, not from other cases that developed earlier after a shorter period of incubation.

Medal Awarded to Dr. Wiley. — Report from Philadelphia states that the Franklin Institute of that city has recently awarded to Dr. Harvey N. Wiley, chief chemist to the Department of Agriculture, an Elliott Cresson medal for "distinguished, leading and directive work in the fields of agricultural and physiological chemistry."

Provision of Rank for Naval Dentists. — In the issue of the Journal for Oct. 27, we commented editorially on the lack of suitable recognition, by the United States government, of dentists in the army and navy. Report from Washington, D. C., states that the House Committee on Naval Affairs has recently reported favorably "a bill entering members of the dental corps as acting assistant surgeons, with provision that after eleven years' service there may be developed from them automatically one lieutenant commander, four passed assistant surgeons and twenty-five assistant surgeons. This bill, if enacted into law, should seem to provide the desired recognition in rank for dentists in the navy, and presumably similar provision in the army might be expected to follow.

The Free Lunch Problem in Schools. — In last week's issue of the Journal we commented on the questionable desirability of furnishing free lunch to public schoolchildren. It is stated that in the open-air school at Indianapolis, Ind., pupils are required to pay three cents each a day for the hot milk, soup or cocoa with which they are supplied, the balance of the cost being paid by the school department. It would seem that in any project for feeding schoolchildren, whether tuberculous or healthy, at least half the expense should be met by the children or their parents, though it is also questionable whether the acceptance of such a half-charity be not as destructive to self-reliance and self-respect as that of a complete bounty or subsidy.

Food Poisoning in Germany. — Report from Berlin states that an entire family of seven persons has recently died at Grandenz, Prussia, of supposed poisoning from impure food, and that during the first week in December there were several hundred cases of similar poisoning in Düsseldorf and Hamburg, with several fatalities in the latter city. It is alleged that a consignment of artificial butter manufactured from rancid French fat was the cause of these poisoning cases. In this explanation, however, there might seem a possible suggestion of racial animus. Any one who has had experience of the German custom of eating raw ham and sausages would not be surprised if this abominable gastronomic usage were proved to be the real source of the trouble.

The Cholera Epidemics. — During the week ending Dec. 10, 29 new cases and 11 deaths of Asiatic cholera were reported from Italy, as against 27 cases and 3 deaths the preceding week. Palermo in Sicily seems now to be the residual center of the infection in that country.

The epidemic of cholera in Madeira, to which we referred in last week's issue of the Journal, has apparently reached considerable proportions. Advices from Funchal, the capital of the island, state that the total number of cases is now 422, of which 136 have died. Riots are said to occur daily, and there is great destitution on account of the cessation of business. It is reported from Lisbon, Portugal, that the Portuguese gunboat *Zaire* has been despatched from that city to Madeira with food supplies, troops and medicines.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston.— For the week ending at noon, Dec. 13, 1910, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 53, scarlatina 34, typhoid fever 14, measles 17, smallpox 0, tuberculosis 51.

The death-rate of the reported deaths for the week ending Dec. 13, 1910, was 16.18.

Boston Mortality Statistics. —The total number of deaths reported to the Board of Health for the week ending Saturday, noon, Dec. 10, 1910, was 226, against 203 the corresponding week of last year, showing an increase of 23 deaths and making the death-rate for the week 17.49. Of this number 118 were males and 108 were females; 218 were white and 8 colored; 124 were born in the United States, 99 in foreign countries and 3 unknown; 42 were of American parentage, 158 of foreign parentage and 26 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 62 cases and 1 death; scarlatina, 31 cases and 2 deaths; typhoid fever, 16 cases and 4 deaths; measles, 18 cases and 1 death; tuberculosis, 51 cases and 15 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 41, whooping cough 0, heart disease 35, bronchitis 4. There were 14 deaths from violent causes. The number of children who died under one year was 33; the number under five years 50. The number of persons who died over sixty years of age was 69. The deaths in public institutions

were 88. Cerebrospinal meningitis, 1 case and 2 deaths. Acute anterior poliomyelitis, 1 death.

Of the above infectious diseases the following were non-residents: Consumption, 1 case. Diphtheria, 1 case. Scarlet fever, 3 cases and 1 death.

Deducting deaths of non-residents, the total is 208 and the death-rate is then 16.10.

CHARITABLE BEQUEST TO A HOSPITAL. — The will of the late Lucretia Dyer, of Randolph, Mass., allowed for probate in court last week at Dedham, Mass., bequeathes her savings-bank deposit to the New England Hospital for Women and Children, Boston.

RECOMMENDED APPROPRIATION FOR CITY HOSPITAL. — The trustees of the Boston City Hospital have recently recommended an additional loan appropriation of $297,800 for the construction of new buildings, and changes and other improvements in the South Department for contagious diseases.

SCARLET FEVER IN HULL. — Six cases of scarlet fever have recently developed among children at Hull, Mass. To prevent spread of the epidemic, the village school has been ordered closed and fumigated and the school-books destroyed. Civilians of the town have been forbidden to enter the government fortifications in the vicinity lest they communicate the infection to the troops stationed there, and members of the garrison have been warned not to mingle in crowds in the town or to go skating on the local pond.

CONVICTIONS IN SALE OF MILK AND VINEGAR. — Before the Boston Municipal Court last week, seven local milk dealers were fined from $10 to $30 for selling milk without a license, most of them after having had their licenses revoked for previous infraction of law relative to sale of milk. Four other dealers were convicted of having for sale milk not up to the required standard, and were fined $10 each. Two were fined $10 each for putting coloring matter in vinegar. Another dealer was charged with having in possession with intent to sell milk not up to the standard, but his case was continued for further hearing.

Before the Malden District Court a large contractor was fined $100 last week for having milk below the standard. In defense his attorney averred that the milk was to be mixed, before sale, with richer milk which should bring the whole up to the standard.

NEW YORK.

RECOMMENDATION FOR ORGANIZATION OF AN AMBULANCE COMPANY. — Among other recommendations of the State Militia Council which Governor White approved on Dec. 2 was one for the organization of an ambulance company at at Albany, to be attached to the National Guard headquarters.

A CENTENARIAN. — Josiah Zeitlein, of Brooklyn, N. Y., said to be the oldest man in that borough, died on Dec. 1 at the age of one hundred and six years. He was born in 1804 in Lodz, Poland, and is stated to have been living with his parents in Moscow when in 1812 the Russians burned that city on the advance of Napoleon. He retired from business in Moscow thirty years ago and came to reside with a son-in-law in Brooklyn. He leaves three sons, the oldest of whom is seventy-six, and fifteen grandchildren. The old man was quite active physically up to the time of his death, and, occupying a room on the top floor of the four-story house, he would each night climb unaided the three flights of stairs. It is related of him that he was accustomed to rise early every morning and, after swallowing some tea, would take several drinks of whiskey, smoke two pipefuls of tobacco, and then go back to bed. Later in the day he would get up again and repeat the performance. He is reported to have attributed his longevity to moderation in these and in all other things.

SPECIAL MILK CONFERENCE. — A special conference on milk was held on Dec. 2 and 3, on the invitation of the New York Milk Committee, and there was a large attendance of sanitarians, as well as milk producers and dealers. Among those present were Prof. W. T. Sedgwick, of the Massachusetts Institute of Technology; Dr. J. W. Kerr, Assistant Surgeon-General, U. S. Public Health and Marine-Hospital Service; Dr. W. A. Evans, Health Commissioner of Chicago; Dr. John Amyot, Health Officer of Toronto; Dr. G. L. Magruder, of Washington; and Dr. Henry L. Colt, of Newark, N. J. John P. Mitchell, President of the New York Board of Aldermen, opened the conference with an address in which he alluded to the large death-rate in infants. He said that the city authorities were anxious to do all in their power to save the children, and finally submitted fourteen questions which, he stated, the Board of Estimate desired to have answered in order to be able to act intelligently in the mat-

ter. There was considerable discussion and much difference of opinion on the matter of pasteurization, and a resolution calling for general pasteurization was tabled. Deputy Attorney-General Coleman advocated the establishment of a non-partisan State Milk Commission, the members of which should be appointed by the governor on the recommendation of milk committees and boards of trade. At present, he said, there was no way of controlling combinations among the large milk companies, and among the other functions of the commission should be the fixing of the minimum price for the producer and the minimum price to the consumer. The New York Milk Committee, which has for its principal objects the improvement of the milk supply of the city and the education of the public in the proper use of milk for infant feeding and other purposes, has decided to call a similar conference annually.

5. Holmes, B. *Diagnosis and Treatment of Osteal Tuberculosis without Abscess Formation.*
6. Cocks, E. L. *The Treatment of the More Common Diseases of the Skin.*

1. Clarke and Curts report a case of sulph-hemoglobinemia, or idiopathic enterogenous cyanosis, as it is sometimes called. This rare condition is probably due to the absorption of an excess of sulphuretted hydrogen from the bowel and can generally be cured by systematic purgation. Suph-hemoglobin is a purple pigment, distinguished from methemoglobin by the spectroscope. Both methemoglobin and sulph-hemoglobin give a black absorption band in the red of the spectrum. The addition of a drop of dilute ammonium sulphide removes the band of methemoglobin, but has no effect on that of sulph-hemoglobin. In both methemoglobinemia and sulph-hemoglobinemia the striking symptom is cyanosis unaccompaned by dyspnea or other signs of cardiac or pulmonary disease. Methemoglobinemia usually occurs in men with chronic enteritis; sulph-hemoglobinemia in constipated women. If the patient is put on a strict milk diet, methemoglobinemia disappears within forty-eight hours. No such effect is produced in sulph-hemoglobinemia. [L. D. C.]

6. Runnels concludes an exhaustive article on the use of the carbon compounds of arsenic in syphilis. He is particularly impressed with the value of pure sodium cacodylate in many cases. This has several decided advantages over Ehrlich's "606" — it is accessible to all in the United States; it is inexpensive; its injection is not painful; it is more stable; it contains a greater percentage of arsenic, and all the arsenic in it is absorbed. 1. Reynolds brings out and emphasizes many important points in treating of the etiology of ptoses and their relation to neurasthenia. He does not believe that the spontaneous relaxation of the supports of some one organ is anywhere near as common as supposed, but that muscular relaxations are always general in their character. Rapid loss of fat is by far the most important element in the causation of this class of cases in which ptosis is the result of purely passive lengthening of the normal supports. In this class of cases operative treatment is almost never indicated. Most of the operative failures are due to the adoption of routine operative measures without determining the cause of the individual ptosis. One of the greatest causes of ptosis is the round-shouldered, hollow-backed attitude which allows of intestinal pressure on the uterus, forcing it backward. In these cases rectification of incorrect posture is the first step, and this is often best done by the proper therapeutic corset instead of by the complicated brace. In nephroptosis, belts and pads to make direct pressure on or below the prolapsed kidney are less effective than a corset which exerts the proper abdominal pressure and support throughout the whole abdomen. One of the most common of the pelvic ptoses are infections of the Fallopian tubes which drag the uterus out of position by adhesive bands.

3. Kaplan believes that only 66 to 88% of tabetics are syphilitic. In patients in the active forms of the disease with a negative Wassermann reaction, mercury did no good, and in some cases harm. The disappearance of the Wassermann reaction from a case of syphilis can only

be taken as a favorable sign, provided the clinical manifestations go hand in hand. The laboratory report on a Wassermann should always be collated with the clinical findings in each case. [E. H. R.]

THE ARCHIVES OF INTERNAL MEDICINE.

4. Hess injected small quantities of Bacillus prodigiosus into the veins of dogs and rabbits, after having tied off and severed the intestine below the entrance of the biliary and pancreatic ducts, and within a few hours recovered the bacillus from the small intestine. The bile, he found, always contained many bacilli, the urine a few, the pancreatic juice practically none.

6. Sweet and Pemberton are conducting a series of experiments regarding the relation of certain ductless glands to pancreatic activity. Since removal of the adrenals causes marked increase in pancreatic secretion, they hold that these glands exercise an inhibitory influence upon the pancreas. There is some evidence to show that the mechanism of this phenomenon has to do with the increase of prosecretin in the duodenum.

7. Brooks reports the case of a young woman, operated upon for chronic appendicitis, who died as a result of receiving by mistake enemata amounting to 9 oz. of concentrated "stock solution" sodium chloride. By putting into the stomachs of rabbits a large dose of the same kind of solution, he obtained similar clinical symptoms. Autopsy showed great concentration of blood, with dryness of some organs, notably the central nervous system, and edema of others. The intestines contained much gelatinous lymph. Brooks suggests that the cerebral symptoms in cholera and other dessicating diseases, and in some cases of poisoning by over-heavy dosage with Epsom salts, may be caused in the same manner.

8. Janeway and Park, from a study of the resistance of arterial walls to pressure, conclude that for clinical purposes the resistance even of atheromatous vessel walls causes an error of no more than 10 mm. Hg. They advise reading the manometer at the moment of return of the pulse wave after compression rather than at that of its disappearance. [G. G. S.]

1. Walker presents twelve cases of atony of the bladder in which there were no signs of organic disease of the nervous system, in which the urethræ were unobstructed and in which the prostates were healthy. The stream of urine did not start promptly and was feeble, often intermittent and sometimes projected only by forced efforts of the abdominal muscles. In one case the urine escaped on coughing. In four cases there was chronic distention of the bladder. Most cases showed a residual urine (4–10 oz.). All cases showed a marked trabeculation of the bladder, usually the lateral walls, occasionally universal (except the trigone). The trabeculation differs from that of an obstructed bladder in that the muscular ridges are fine, evenly set, and with regular branchings rather than thick, irregular and with uneven branchings, and the interspaces are shallow and usually saucer-shaped rather than deep and narrow. Walker believes this trabeculation is a hypertrophy of intact muscle-bundles subsequent to a primary atrophy of a greater or less number of muscle bundles dependent upon some lesion of the sympathetic reflex center.

2. Bottomley places on record a congenital complete stricture of the left ureter one and a half inches above the bladder, in a boy of six. The hypernephrotic kidney and its ureter dilated to the size of a small intestine were successfully removed. He has collected and epitomized 55 other cases, 17 showing protrusion into the bladder, and the remainder without such protrusions. The paper is a comprehensive study of congenital ureteral strictures, partial, complete or accompanied by aplasia (imperfect development), which open, or were evidently intended to open, into the urinary bladder. Sex had no particular influence. The defect may be immediately incompatible with life, may soon become so, may remain latent a greater or lesser period until infection occurs, or may exist unsuspected during life and be found at autopsy after death from other causes. Forty-five cases occurred in single ureters, 11 in supernumerary ureters. With the exception of great rareties, the stricture in single ureters is usually in or very close to the bladder. The blind end at the stricture may be just beneath the bladder mucosa, in the bladder muscle layer, or may just reach the outer bladder wall (rather unusual). The ureter is almost invariably dilated, thin-walled (rarely thick), and tortuous (perhaps having appearance of string of sausages). Hydronephrosis of varying degree is the rule, but marked primary atrophy may result from strictures of the same location and character. Some cases are symptomless. Other cases present so varied a symptomatology that no single symptom or symptom-complex definitely indicates the condition. The urine is usually negative, although hematuria may occur.

4. Braasch presents the results of further studies in pyelography. He usually uses a 10 to 15% collargol solution. Dilated pelves are beautifully demonstrated, even when the catheter does not pass the etiologic ureteral obstruction, for in such cases enough collargol can frequently be injected past the obstruction to outline the pelvis quite definitely. The site of obstruction is furthermore shown. A pelvis dilated from mechanical obstruction casts a regular shadow — even lines of the pelvic wall and rounded ends of the dilated calyces. An inflammatory pelvis casts an irregular shadow, often associated with detached shadows from cortical abscesses connected with the pelvis. A tumor may distort the pelvis by retraction, in which case the pelvis may be irregularly large or a single calyx may be distended even three or four inches, or the ureteropelvic juncture may be abnormally broad or square. A tumor may distort the pelvis by encroachment, in which case only narrow slits may persist or complete obliteration may occur. In possibly a third of the cases of renal tumor the pelves may not be sufficiently distorted to produce distinctive shadows. Braasch has found pyelography valuable, also, in the differentiation of abdominal tumors, extrarenal and renal shadows; in horseshoe, median-lying

and solitary kidneys; in cystic kidney; in hydro-ureter; and in ascertaining renal functional capacity.

11. Thomas reports further success with his forceps-tourniquet first described in 1898. The instrument is somewhat similar to Doyen's stomach-clamp. One blade, the internal, has rounded edges and tip. The other blade is roughened to prevent slipping and has a shoulder to prevent compressing the skin near the articulation of the blades. In amputating at the hip a stab puncture is made just below the anterior superior spine of the ilium, through which the internal blade is forcibly pushed toward the neck of the femur in a direction parallel to Poupart's ligament. The leg is exsanguinated as much as possible by vertical elevation. The forceps is then clamped, effectually and simultaneously compressing the femoral vessels. Upon turning up the anterior flap the vessels are seized with hemostats and the clamp removed. Vessels in the posterior flap are controlled by applying the clamp behind the neck of the femur. [T. W. H.]

3. Crouse considers that the diagnosis of malignant disease of the appendix is practically never made before operation or autopsy. The symptoms are those of appendicitis. The disease, however, is not rare. Simple removal of the appendix generally effects a cure, particularly in the sphenoidal cell type. The growth is generally found as a small hard nodule at the distal end of the organ. Many authors comment on the early years at which this disease is found. The prognosis, with removal before any extension has occurred, is excellent.

8. Quinby's paper on intratracheal insufflation is most interesting and practical, illustrating an entirely new and simple means of preventing operative pneumothorax. It takes advantage of the principle of internal respiration, and by means of a properly loosely fitting soft rubber tube introduced nearly to the bifurcation of the trachea, a continuous interchange of oxygen and carbon dioxide is effected without the necessity of the respiratory movements of the lungs or the chest wall. The patient is breathed for instead of breathing. By this method the interchange of oxygen is so perfect that it is impossible to over-etherize a dog with the intratracheal tube working. It also does away with the very cumbersome and expensive differential pressure cabinets and chambers. It is a method which is simplicity itself and deserves thorough trial by many workers and surgeons. [E. H. R.]

3. Morison and Drummond describe an interesting and rare class of fibrous tumors which occur in the muscles or muscular fasciæ of the abdominal wall which possess certain characteristics apart from fibromata elsewhere. Such tumors they call "desmoid tumors." They are rarely found in connection with other muscles. Their association with pregnancy is so frequent as to constitute more than a coincidence. Possibly traumatism, by muscle stretching or tearing, is of etiologic significance. A firm but not tender sausage-shaped tumor with some mobility across, but not in the direction of the fibers of the relaxed muscle with which it appears to be associated, fixed when the muscle is made tense, and occurring in a woman recently pregnant, is a desmoid tumor. The treatment is immediate excision.

5. Boutor gives the details of an interesting case of primary acidosis. The rarity of this condition and the difficulties of differential diagnosis make the report of the case of some value. [J. B. H.]

7. Willcox and Collingwood, after a careful study of the therapeutic effects of alcohol vapor mixed with oxygen, conclude (1) that oxygen bubbled through absolute alcohol is a marked cardiac stimulant in cases of heart failure, and that it is pleasant and non-irritating, causing no ill-effects to the lungs or bodily system. (2) A rapid feeble pulse is slowed by some ten to twenty beats with marked improvement in its force and volume. The blood pressure is raised from 10–30 mgm. The full effect is obtained after five minutes and lasts for several minutes afterward; as it passes off it should be repeated.

12. Ward describes certain studies he has made, which go to show that the phenomenon occasionally seen in blood known as polychromasia or polychromatophilia is a regenerative one and not degenerative. All normal blood is potentially polychromatophilic, only under certain stimuli these cells are more in evidence. [J. B. H.]

5. Frankenstein mentions the fact that in kidney disease a salt-free diet is urged. In eclampsia, when there is evidence in the urine of kidney disease, it is frequently advised to give enormous quantities of salt solution intravenously or subcutaneously. He asks, Is this rational? and cites cases which might be used to answer the question either way. In cases of heart collapse approaching he considers the infusions dangerous. [C. F., JR.]

2. Rolly says that his studies on humans have led him to the conclusion that in a great number of patients during the course of various diseases a negative cutaneous tuberculin test occurs; and that in convalescence it becomes positive. He believes the change due to modifications in the skin rather than to changes of immunity.

4. Although not entirely new, the observations of Zabel have been so thoroughly carried out that the results merit the attention of all who use the blood-pressure test in clinical work. The patients were put on a routine mode of life and pressures were taken daily at the same hour and under similar circumstances. He says in conclusion that the normal blood pressure is subject to irregular variations which differ in individuals; that stimuli of all sorts can produce a rise of blood pressure temporarily; and that the variations in a series of fifty measurements taken under the same circumstances is generally greater at first than later.

If the cuff of the apparatus is cold when applied, if cold air strikes the arm of the patient, or if he is frightened or hurt by the apparatus, a rise of blood pressure may follow. Neurasthenic or hysterical people and convalescents from acute disease generally show greater variations of blood pressure due to psychic influences or external stimuli than do normal individuals. These variations may be so great as to lead to wrong conclusions if their cause is not appreciated. (The article should be read to be appreciated.) [G. C. S.]

6. The author reports the case of a patient who came to him with the complaint that she was passing bits of bone with her stools. The patient was taken to the hospital, where examination revealed that just above the sphincter ani was a hole in the anterior wall of the rectum containing many bones. This was thoroughly cleaned out and besides some forty bones and the calcified larynx of an apparently seven months' old fetus, shreds of tissue and blood clot were also found. The cavity was then washed out and packed with iodoform gauze. This was gradually removed and patient made a speedy recovery, improving very much in general condition. The patient at first gave no history that could explain the condition, but later gave the fact that some five years before a supposed pregnancy terminated with sharp pain in the lower abdomen and a gradual return to her normal figure. This case, with others quoted from the literature, is advanced as evidence that in cases of probable extra-uterine pregnancy an operation should always be performed to save the patient from subsequent suffering and danger. [J. L. H.]

2. Schlaepfer reports on the histologic appearance of the intestinal mucous membrane in pernicious anemia. Throughout the large and small intestine he found areas of slight chronic inflammation in the mucous membrane. These areas were marked by infiltration of cells of the lymphocytic series. Also there was proliferation of the lymph follicles. In these chronic inflammatory areas were small nucleated fat-containing cells which he considered a further example of a slight inflammatory process.

4. Jemma reports on some cases of infantile anemia from which, by splenic puncture, a parasite similar to the parasite of Leishman was obtained. He experimented with this parasite by injecting blood from the spleen of these cases into dogs and had fairly successful results in showing that the disease could be transmitted by inoculation. The parasite is very similar to that which causes kala azar, but he does not consider that this tropical disease and his cases of splenic anemia are the same disease.

5. Koll reports several cases of chronic foul diarrheas which show bone changes by means of the x-ray. Some of these cases improved in regard to their bone symptoms when the diarrhea was relieved. He considers there is some relation between the intestinal putrefaction and the bone injuries.

6. Abend emphasizes the importance of searching the sputum for evidences of animal parasites in cases of hemoptysis in which tuberculosis can be excluded. The eggs may frequently be found in the sputum. [C. F., Jr.]

Obituaries.

JOHN CUMMINGS MUNRO, M.D.

Dr. John Cummings Munro died at his home in Boston, Dec. 6, in his fifty-third year. Dr. Munro was born in Lexington, Mass., March 26, 1858. He came of distinguished ancestors; his grandfather took part in the battle of Lexington, and four professors, all bearing the name Alexander Munro, for upwards of a hundred years filled the chair of anatomy and surgery at the University of Edinburgh.

Dr. Munro received his preliminary education at the Boston Latin School and Harvard University, receiving his degree of A.B. in 1881, and the degree of M.D. from the Harvard Medical School in 1884. As was customary at that time, he began active work as a general practitioner, but his interests soon began to turn to surgery, a branch of medicine in which he early made a distinguished place for himself. From 1889 to 1905 he was connected with the Harvard Medical School in a teaching capacity. He was assistant in anatomy from 1889 to 1903, assistant demonstrator of anatomy the following year; thereafter he held respectively the position of assistant in clinical surgery, instructor in surgery and lecturer in surgery. It will be seen, therefore, that his special training for surgery came through a long course of anatomical teaching, which, no doubt, accounted, at least in a measure, for his exceptional skill. In addition to his teaching positions, which he never allowed to occupy an undue share of his time, he was surgeon at the Boston City Hospital for ten years, from 1893 to 1903, when he resigned to accept the position of surgeon-in-chief at the Carney Hospital, instituting thereby the first continuous surgical service in New England. He was also consulting surgeon to several suburban hospitals. His society membership was large. Among the organizations to which he belonged were the American Surgical Society; the Society of Clinical Surgery, of which he was president in 1905; the Association of American Anatomists; the American Medical Association, in which he always took a deep interest and in which he was chairman of the Surgical Section in 1909; The Massachusetts Medical Society; the Southern Surgical and Gynecological Association; the Boston Society of Medical Sciences; the Boston Society for Medical Improvement, together with various honorary memberships.

The work which proved to be Dr. Munro's greatest opportunity for development was undoubtedly the surgical clinic at the Carney Hospital, over which he presided with rare judgment for seven years. Not only did this continuous service give him an opportunity to carry on surgical work in the most satisfactory possible way, but it also demonstrated the usefulness of such a continuous service, in regard to which there have been differences of opinion in this community. Under his administration the Carney Surgical Clinic became widely known and much visited by men in search of high ideals of work, and by those interested in the progress of medicine in general. An attempt was also made at this clinic, and with a marked degree of success, to avoid the abuse of medical charity. Those who were able to pay for services rendered were expected to do so, while the deserving poor were treated free of charge as at other public hospitals.

Dr. Munro's contributions to medical literature were numerous, though not so extensive as those of many men of less mark. He wrote only when he believed he had a mission, and not infrequently his contributions assumed a somewhat militant tone. He was an ardent and uncompromising believer in surgical procedures and had small patience with the conservative members of the profession who counciled delay in surgical

measures which, to his mind, gave promise of more immediate relief. He was a man of marked definiteness of opinion but was always fair in discussion, spoke keenly and to the point and never allowed words to obscure thought. One of his last contributions to medical literature was the annual discourse before The Massachusetts Medical Society delivered on June 8 of this year. His subject was "Dyspepsia and Indigestion viewed from a Surgical Standpoint." The final paragraph of this excellent paper sums up his general attitude toward medical problems so well that its quotation here is justified. "To conclude very briefly I would again beg the general practitioner to consider the probability of some simple surgical lesion of the abdominal viscera in his cases of persistent recurrent indigestion; that where such a lesion does exist surgery is the safest and surest means at our disposal to bring about a permanent cure; that his neurotics with indigestion secondary to surgical lesions have the right of relief from their local trouble; that finally there is a type of dyspepsia most naturally ascribed to gastroduodenal ulcer, but which is really secondary to an appendicitis, and which is curable to a degree not yet definitely determined, by a simple appendectomy."

As a surgeon, Dr. Munro was distinguished for his dexterity, his judgment and his fearlessness in undertaking operations before which a less skilled man might well have hesitated. His success and his personality were such that he had a very large following, and he undoubtedly added greatly to the science and art of surgery in this community, and indirectly in the country at large. As a man, he was modest, honest, simple and clean in life, and straightforward in all his actions. To those who knew him well, he was a delightful companion and a firm and uncompromising friend. As was natural in such a personality, he had a strong and beneficent influence upon younger men and undoubtedly did much to encourage many struggling practitioners, although for some years before his death he had not been brought into close contact with medical students. He met his last distressing illness with the courage and determination which one would have expected from such a character as his. He was to an unusual degree devoted to his professional work and enthusiastic in its accomplishment. Death was to him particularly unwelcome, since at the age of fifty-three his work was far from completed and his enthusiasm for his chosen field of endeavor was waxing rather than waning. In spite of this, he died with heroism and with the sympathy of his colleagues and friends to a degree hardly to be expressed in words. In his private life, Dr. Munro showed the same attributes as in his professional work. He was a devoted father and husband and gladly gave what time was not devoted to his profession to the interests of his family. He was skilled as a musician, an interest which he had fostered since his college days when he had taken active part in his college orchestra and similar musical organizations.

He was married on Nov. 17, 1887, to Miss Mary Squibb, of Brooklyn, N. Y., who always followed his professional career with peculiar interest and sympathy and often accompanied her husband to medical meetings in various parts of the country. So definite was Dr. Munro's attitude toward medical questions, and so pronounced his opinion on many matters of medical or surgical import, that his place will not soon be filled or the memory of his personality and of his accomplishment fade.

CHRISTIAN ARCHIBALD HERTER, M.D.

DR. CHRISTIAN ARCHIBALD HERTER, of New York, professor of pharmacology and therapeutics in Columbia University, died from pneumonia on Dec. 5, in the forty-sixth year of his age He was born in Connecticut, and was a maternal grandson of Dr. Archibald Miles of that state. He has graduated from the College of Physicians and Surgeons in 1885, and afterwards took up post-graduate work under Professors Welch, of Johns Hopkins University, Baltimore, and August Forel, of Zürich, Switzerland. Inheriting wealth, he never engaged in private practice. At first, he devoted himself more particularly to the study of neurology, and wrote a textbook on the "Diagnosis of Diseases of the Nervous System," which was published in 1892. Later, he gave his attention largely to the chemical aspects of disease. He early fitted up a splendidly equipped laboratory in his own home, and his original research work attracted widespread attention in the profesion. His studies in metabolism, the physiology and pathology of the intestinal tract, the etiology of arthritis deformans, and the action of adrenalin on the pancreatic secretion were among many investigations of his which proved of great interest and value. From 1897 to 1903 he was professor of pathological chemistry in Bellevue Hospital Medical College, and on resigning that position to accept the chair in the Columbia Medical School he established the Herter lectureship at Bellevue. Under this, courses of lectures have been given by such distinguished foreigners as Von Noorden, Halliburton Friedrich Müller, Starling and Cohnheim. He also established a similar lectureship at Johns Hopkins where lectures have been given by Ehrlich, Von Meyer, Schaefer and Chiari.

For ten years he was visiting physician to the City Hospital on Blackwell's Island, and at the time of his death was consulting physician to this hospital. He was a member of the Reference Board, appointed by President Roosevelt, to investigate the influence of food preservatives on the human body, and his studies on this subject were conducted in his own laboratory. From the beginning, he was one of the directors of the Rockefeller Institute for Medical Research, and during the last two years he had devoted much time and study to the plans for the hospital of the institute, to which, on its opening recently, he was appointed chief physician.

Dr. Herter has been indeed a pioneer in research, and his untimely death is deeply deplored,

for, remarkable as were his achievements, it may well be believed that had his life been spared he would have accomplished still more brilliant results and left a record such as is seldom made.

JOHN CHALMERS DA COSTA, M.D.

Dr. John Chalmers Da Costa, who died on Dec. 6 at Philadelphia, was born in that city on Nov. 15, 1863. He graduated from the scientific department of the University of Pennsylvania in 1882, and in 1885 received the degree of M.D. from the Jefferson Medical College. He served at the Philadelphia Hospital as resident physician in 1885–6, and as assistant physician in the insane department in 1886–7. In 1887 he became assistant demonstrator of anatomy at the Jefferson Medical College, and later demonstrator and professor of surgery. Since 1895 he had been surgeon to the Philadelphia Hospital and since 1896 to St. Joseph's and St. Agnes hospitals. At the time of his death he was president of the Philadelphia Obstetrical Society, a fellow of the American Surgical Association and the College of Physicians of Philadelphia, and associate member of the Society of Gynecology and Surgery of Bucharest. He was author, or editor, of several important medical works and a frequent contributor on surgical subjects to scientific periodicals. His death unhappily terminates the activity of a distinguished member of a distinguished American medical family.

Miscellany.

CLASSIFICATION AND EXAMINATION OF MEDICAL INSPECTORS OF SCHOOLS.

In last week's issue of the Journal we commented on the proposed change in the number and salary of school physicians in Boston. The following letter from the chairman of the Civil Service Commission to one of the daily newspapers relative to the classification and examination of medical inspectors of schools seems timely and deserving of republication:

"In a recent interesting editorial your paper speaks of 'the action of the Civil Service Commission in permitting the Boston Health Board to appoint school physicians without previous examination for fitness.'

"It occurs to me that the general public may be interested in a fuller statement of the situation. For some years physicians have been appointed by the Health Board to inspect schoolchildren and have been designated in the pay-roll lists as 'medical inspectors.'

"The Civil Service Commission has considered these persons as subject to the civil service law and rules; but, owing to the small salary paid, the probable difficulty of establishing eligible lists and the pressure of other duties, it has never held an examination.

"When the question of the appointment of the proposed new school inspectors, at a reasonably high salary, arose, the commission informed the Health Board that it considered the positions classified under the civil service law and rules, and that it would probably hold an examination. Such an examination would be based wholly on the physician's training and experience and upon his technical qualifications for the place.

"At the request of the school board, the commission presented to the attorney-general, its official legal adviser, the question whether or not these school physicians were subject to the civil service law and rules and classified as 'inspectors.' The attorney-general ruled, this autumn, that the positions were not classified.

"This ruling, therefore, has taken the positions out of the jurisdiction of the commission and thrown all appointments into the hands of the Health Board, unrestricted by any requirements, except such as that board itself shall fix.

"'As exactly similar positions in New York City and in other large cities are subject to the civil service law, and as it seems highly desirable that appointments to such positions should be made solely on merit and without regard to other influences, it would seem highly desirable that legislation should be enacted subjecting the positions to the civil service law. In making this suggestion, however, I do not mean to intimate that the appointments by the Health Board will be made on qualifications other than merit, but I feel that such positions should by law be removed from the possibility or attempts to introduce other considerations."

Correspondence.

"INFECTIOUSNESS AND PROPHYLAXIS OF CROUPOUS PNEUMONIA."

Boston, Dec. 2, 1910.

Mr. Editor: Your timely editorial upon the infectiousness and prophylaxis of croupous pneumonia is of great interest and importance. Only in one instance, but that a very noticeable and serious one, must I differ from your statements and advice. In regard to nightly cleansing of the "nose, throat and mouth," so many people take your advice literally and actually try to cleanse the nose by artificial means that a renewal of warnings issued by ear specialists forty years ago should be added to any suggestions of this sort. The very serious inflammatory processes within the middle ears and extending to the brain or to the mastoids from infectious material actually forced into the tympana by nasal douches or by post-nasal syringing have caused so much trouble for patients and aurists that such warnings are pertinent. On the whole, it is unsafe to make use of any fluids for "cleansing the nose." The reason for this is obvious to all who have studied the anatomy and physiology of the upper air passages. The initial source of infection must necessarily be placed where ordinary methods of "cleansing" cannot prevail. By these I mean the action of the ciliated epithelium, to bring particles outwards by forcible blowing of the nose and by swallowing. The acts of coughing and of sneezing, the latter not volitional, are somewhat effective.

The location of the only "site of infection" is behind the nose, and upon the nasopharyngeal wall. At this spot is situated the first tonsil, named after Luschka, who described it. Without going into detaills, it may be stated that this tonsil is usually hypertrophied or hyperplasic, in either case not normal; consequently any increase in the amount of work required of it cannot be performed. Its functions then are impaired, and if during the time when it is pathologic any excessive amount of virulent microorganisms invade it, they may develop without interference from phagocytes to produce soluble toxins which,

together with bacilli, enter the economy through the lymph channels.

A proper "cleansing of the nose" must mean partial or complete sterilization of the "site of infection" in the nasopharynx. This can never be accomplished by anything short of direct application to the diseased surface of sterilizing agents or of stimulants. These should be used regularly in cases of badly diseased throats and frequently in cases of acute infections. Their value as preventive measures in health is purely psychological.

Very truly yours,
EDMUND D. SPEAR, M.D.

STAINING CAPSULATED BACTERIA IN BODY FLUIDS.

NEW BRIGHTON, STATEN ISLAND, N. Y.,
Dec. 1, 1910.

Mr. Editor: Referring to the article published in the BOSTON MEDICAL AND SURGICAL JOURNAL, date of Nov. 24, on "A Method of Staining Capsulated Bacteria in Body Fluids," I would like to add a very simple method of staining capsulated bacteria which I have found to give uniformly good results and using only stains that would be found in the smallest office laboratory. It is almost the same method so long used for staining the tubercle bacillus except that no decolorizing methods are used.

The thinly spread smear is fixed by heat in the usual manner, covered with Ziehl's carbol-fuchsin solution and steamed gently for one to two minutes. Wash in water and cover with methylene blue, 1% solution, for one-half minute, warming gently. Wash in water, dry and the specimen is ready to be examined. The capsules appear as very clear and distinct areas about the dark-blue stained micro-organisms.

Very truly yours,
HENRY A. CRAIG, M.D.,
Assistant Physician and Bacteriologist,
Sailors' Snug Harbor Hospital.

ANATOMIST (MALE).

ARMY MEDICAL MUSEUM.

THE United States Civil Service Commission announces an examination on Jan. 18, 1911, to secure eligibles from which to make certification to fill a vacancy in the position of anatomist (male), at $1,600 per annum, in the Army Medical Museum, Office of the Surgeon-General, and vacancies requiring similar qualifications as they may occur, unless it shall be decided in the interest of the service to fill the vacancy by reinstatement, transfer or promotion.

SOCIETY NOTICE.

BOSTON MEDICAL LIBRARY IN CONJUNCTION WITH THE SUFFOLK DISTRICT MEDICAL SOCIETY.—Surgical Section meeting, John Ware Hall, Wednesday, Dec. 21, 1910, at 8.15 P.M. "Non-Malignant Strictures of the Rectum." Dr. James P. Tuttle, New York. Discussion by Drs. F. B. Harrington, C. L. Scudder, T. C. Hill, F. J. Cotton and J. S. Stone. Light refreshments after the meeting.

WILLIAM C. QUINBY, M.D., *Secretary,* 396 Marlborough St.
CHARLES A. PORTER, M.D., *Chairman,* 254 Beacon St.

RECENT DEATHS.

MUNRO, JOHN CUMMINGS, M.D., M.M.S.S., died in Boston, Dec. 6, 1910, aged fifty-two years.

DR. HORACE BABCOCK, a retired physician of Gowanda, Cattaraugus County, N. Y., died on Dec. 6, in his eighty-seventh year. He was a graduate of the medical department of the University of Buffalo, and practised in Wisconsin until 1862. He then was appointed surgeon of the Second Wisconsin Regiment, and while serving in this capacity was captured at Gettysburg. After the war he located at Gowanda.

DR. JOB B. M. DICKINS, who died of cerebral hemorrhage last week in Newburyport, Mass., was born at Haverhill, Mass., in 1845. He obtained his medical education partly in Cincinnati, partly in New York. He practised at first in Cambridgeport, Mass., but removed later to Newburyport.

DR. JAMES DUNN, of Winthrop, Mass., who died of bilateral pneumonia last week at the Boston City Hospital, was born in 1883. He was a graduate of the Tufts Medical School. He is survived by his mother, one sister, and one brother.

DR. HENRI HUCHARD, of Paris, France, died in that city on Dec. 11. He was a specialist on diseases of the heart.

MCDONALD, JAMES ATHANASIUS, M.D., M.M.S.S., retired, died in Charlestown, Dec. 8, 1910, aged seventy years.

DR. JAMES ATHANASIUS MCDONALD, who died of pneumonia on Dec. 8, in Charlestown, was born in Charlottetown, P. E. I., on May 2, 1840. In 1866 he received the degree of M.D. from the Harvard Medical School, and immediately settled in the practise of medicine in Charlestown. In addition to the activities of a busy professional life, he served in 1875 as a representative to the General Court, and for many years as a member of the school committee. From 1870 to 1874 he was surgeon to the Ninth Regiment. He is survived by his widow, one daughter, and two sons, likewise physicians.

DR. WALTER H. WENTWORTH, who died of cerebral hemorrhage last week, at Providence, R. I., was born in Stockbridge, Mass., on March 7, 1841. After graduating from the College of Physicians and Surgeons, New York City, he entered the Union Army and served as a surgeon throughout the Civil War. In 1869 he settled in Pittsfield, Mass., where he had continued in practise ever since. He was a member of the Berkshire Medical Society. He was a widower, but is survived by four children.

THE CARE AND MANAGEMENT OF THE TABETIC BLADDER. 1. DIAGNOSIS.

BY J. DELLINGER BARNEY, M.D., BOSTON,

Assistant Surgeon to the Genito-Urinary Out-Patient Department, Massachusetts General Hospital.

(From the Genito-Urinary Out-Patient Department, Massachusetts General Hospital.)

In this paper I shall discuss the bladder disturbances of tabes dorsalis with special reference to their diagnosis with the cystoscope. In a second article I shall attempt to explain them, while in a third article I shall deal with their prognosis and treatment.

The following case was seen in the Genito-Urinary Out-Patient Department of the Massachusetts General Hospital in February, 1909.

M. S., fifty years old, born in Turkey.

Past history. — Unimportant. Denies venereal disease.

Present illness. — For the past two months some difficulty of micturition.

Stream starts slowly and sometimes stops. Never had to be catheterized. No pain, no incontinence. Frequency, day three or four times; rarely gets up at night.

Physical examination. — Abdominal examination shows distended bladder. Rectal examination shows small, normal prostate. Residual urine, 16 oz. (on two occasions). Urine clear, amber, acid, specific gravity 1,021, no albumen or sugar. No. 30 French sound goes easily to bladder.

Cystoscopy by Dr. Lincoln Davis. Bladder normal except for *marked trabeculation*. Ureters normal; prostate does not protrude into bladder.

In other words, there was no mechanical obstruction to the outflow of urine.

The case was then sent to the Nerve Department for their opinion.

The pupils were irregular, right larger than left, and did not react to light (Argyll-Robertson pupil). Patella and Achilles tendon reflexes present and equal. Romberg's sign absent. On this basis a diagnosis of early, high tabes was made. The patient has since been lost sight of.

After seeing this case it occurred to the writer that a study of a series of similar cases might prove valuable, not only from a diagnostic but also from a therapeutic point of view. This investigation has convinced me that far too little attention is given to the bladder in tabes, and that a great deal can be accomplished by careful, systematic treatment of the urinary tract.

An examination of the literature shows that disturbances of micturition are often the first, and always one of the commonest, symptoms of tabes dorsalis, as well as of many other diseases of the spinal cord. Indeed, as Gowers says, "It may be only for them that the patient seeks medical advice." One might go further and say that the genito-urinary surgeon not uncommonly sees patients "for diagnosis or treatment where from the symptoms only an organic bladder or prostatic lesion has been suspected" (Squier).

The frequency of bladder symptoms has been noted by Erb (80%), Bramwell (74.1%), Häuel (75%), Starr (80%), Gowers, Frankl-Hochwart, Oppenheim, Hirt, Neuhaus, Böhme and Sachs; indeed, by all who have looked into the subject.

That these disorders of micturition may often be the earliest of all symptoms is also agreed to by most. With this evidence in mind it seems to me that the importance of an early and complete investigation of the urinary tract in all cases of tabes cannot be overestimated.

These disturbances are many and varied. Usually a certain sluggishness of micturition is first noticed; the stream starts with difficulty, and cannot be hastened except by considerable effort. The desire to urinate may be infrequent, occurring only once or twice perhaps in the twenty-four hours. Occasionally complete retention is seen at the outset. Following this, or combined with it, there is often slight incontinence, usually at night. Or the patient complains that during coughing, sneezing, sudden muscular effort, etc., a little leakage of urine occurs. This is a very characteristic symptom. This "patchy" nature of the symptoms I consider to be of great diagnostic value. As the disease progresses complete retention (requiring catheterization), incontinence (usually the overflow from a full bladder, and necessitating the use of a urinal), or even an alternation of the two may supervene. Micturition is seldom painful, but true vesical and urethral crises may occur. Erb lays some stress on the early occurrence of dysuria and hyperesthesia of the bladder neck.

As to the objective symptoms, investigation has shown that distinct and important organic changes take place in the bladder before any hint of it is conveyed to the patient or physician. These were noted long ago by Orth, Birch-Hirschfeld, Ehrlich and Brieger, Hirt, and by Nitze in his pioneer work with the cystoscope.

Recent investigators, notably Böhme, Rinaldo, Frohnstein, and Walker, have shown in the cystoscopic examination of the bladder in tabes that these changes, consisting in the formation of the well-known "trabeculæ," may, and do occur before any other manifestation of the disease.

In his recent article Böhme has arranged his findings into four divisions which seem to the writer correct and reasonable.

1. The stage of development of the trabeculæ. There are no objective or subjective symptoms, and the condition is demonstrated only by the cystoscope.

2. The bladder reaches the climax of its compensatory power, and residual urine begins to accumulate. The condition is not yet known to the patient, and cystoscopy alone reveals the condition. A single catheterization may, however, reveal the diagnosis.

3. The stage of residual urine. Now the patient has his first subjective symptoms, weak stream and difficulty of micturition, but no real trouble.

4. This stage is characterized by an increase of all symptoms, real difficulty of micturition occurs, and urination is aided largely by the pressure of the abdominal muscles. Residual urine increases, the bladder is finally overstretched, and

overflow retention occurs. At this stage the patient usually seeks relief from his physician, and it is at this time that trabeculation of the bladder is first observed. As residual urine begins to collect, infection may occur at any time, superimposing the symptoms of cystitis on those already mentioned. As Böhme says, the transition from one stage to another is always gradual, and I might add that the order of events may be somewhat changed.

Since the appearance of the case reported at the begining of this paper, I have made careful examinations of twenty-four cases of tabes dorsalis, all in men; I have also examined one case with a diagnosis of ataxic paraplegia with cerebral syphilis, whose symptoms were essentially those of tabes. Most writers agree that in cord lesions with involvement of the posterior columns, or of the lateral pyramidal tracts, the urinary symptoms may be the same. These cases have occurred in my own practice, and in the neurological clinic at the Massachusetts General Hospital (to whose physicians I am grateful for their courtesy and co-operation). The patients were taken as they came, no selection being made except in the exclusion of cases showing any mechanical obstruction of the urinary tract such as stricture and hypertrophy of the prostate.

In over 90% of my cases there was more or less disturbance of urination. These were as follows, the arrangement being that of their frequency, but not necessarily of their order of appearance.

	Cases.
Difficulty of micturition (including hesitancy and a feeble stream),	15
Incontinence (diurnal),	11
Incontinence (nocturnal),	8
Painful micturition,	6
Urgency,	5
Frequency,	3
Retention,	2
"Does not feel as if he emptied his bladder,"	2
Incontinence with coughing, etc.,	1

In three cases there were no urinary symptoms whatever.

As regards duration, these symptoms had existed in five cases for six months, in six cases for one year, in seven cases for two years, and in five cases for five years or more.

It is significant that in over 50% (12 cases) the urine was cloudy and contained pus. In three of these a culture of the urine showed a pure growth of bacilli of the colon group. As this is by far the commonest organism found in infected urine, I have no reason to doubt that it was the offending germ in all.

The presence of infection in so large a per cent of these bladders is entirely in accord with the observations of others, such as Sachs, Gowers, Böhme, Erb, Squier, Oppenheim and Bramwell. All agree that infection occurs in the last stages of the disease, but that it may appear at a comparatively early date is not given the importance to which it is entitled. Infection of the urinary tract is sure to come sooner or later in any case of obstructed bladder with residual urine. In most of my cases it was clearly autogenous; in a few instrumentation could be held responsible. This infection is of the utmost importance from a prognostic point of view because it eventually leads, without proper treatment, and often even in spite of it, to the more serious condition of pyelitis and pyelonephritis.

In my series the condition of the bladder was noted in 23 cases. Of these, 12 had cystitis, indicated by injection or edema of the mucosa, often only that of the trigone and surface of the prostate. The percentage of cystitis corresponds, therefore, to that of urinary infection. In the other 11 the bladder is recorded as normal.

In 17 cases where the condition of the ureteral orifices was noted, no definite evidence of their involvement was found.

As it was considered unnecessary and even unwise in these cases to catheterize the ureters, no definite data is at hand as to the occurrence of pyelitis and pyelonephritis. In one or two cases it was thought that cloudy urine could be seen issuing from the ureters, but such an observation by inspection only is apt to be faulty. If renal infection existed in any of these cases it was not sufficiently advanced to cause symptoms. This does not eliminate it, however, for, in the first place, it is well known that pyelitis may go on for a long time without symptoms referable to the kidney, and, secondly, these cases were all in fairly good condition and well able to visit the hospital as often as was necessary. But that a fatal ending in many tabetics is caused wholly or partly by urinary infection is the experience of most observers. I shall bring this out more fully in my third paper.

In this connection it is of great importance to find that the urine was clear and sparkling in the three cases having no urinary disturbances.

A matter of equal importance is the presence of residual urine, noted especially by the recent observers already mentioned. This was found in 19 of my cases, absent in 5. The amount varied from 1 oz. to 3 pints, and was found to vary considerably on different occasions in the same individual. It was also greatly reduced after the beginning of treatment, as I shall point out later. Residual urine was not found in those cases with no urinary disturbance, and further, in the absence of residual urine, there was no infection. Hence the sequence of residual urine, bladder symptoms and infection, as was pointed out by Böhme and other writers, and as is shown in my own cases. I believe this combination to be invariable.

A cystoscopic examination was done in all cases. As a preliminary measure, and to exclude any case with mechanical obstruction, the urethra was explored with bougies or sounds, and the prostate was examined through the rectum. No case whose urethra did not admit a No. 26 French sound (meatotomy was done in some cases) or whose prostate could fairly be said to be enlarged was considered. Furthermore, all cases were eliminated where intravesical enlargement of the prostate was shown by the cystoscope. Each

bladder, with one exception, was viewed with the standard amount of fluid (150 ccm.) in order that, so far as possible, the results might be uniform. When possible each case was given urotropin, gr. v, t.i.d., for forty-eight hours previous to the cystoscopy, and all have been instructed to take it continuously. In the majority of the cases the passage of the cystoscope was absolutely painless, no cocainization being required. This is of considerable diagnostic value, as I shall show later. In a few cases the neck of the bladder was hypersensitive.

Twenty-two of the twenty-five bladders (over 80%) were trabeculated. This was the condition found by Böhme in all of his 8 cases, by Frohnstein in all of his 20 cases, by Rinaldo in 1 case. Thus in a total of 54 cases, 51, or over 90% of the bladders, showed trabeculæ. In addition to this we have the word of Walker that, in 31 tabetics cystoscoped by him, "some degree of trabeculation was usually present."

As regards the distribution of the trabeculæ, I am entirely in accord with the writers mentioned above. In the large majority of cases, especially the earlier ones, the trabeculæ are seen to involve particularly the fundus and side walls, while the whole trigone is normal. This is in distinct contrast to the appearance of a bladder obstructed by a stricture, or enlarged prostate. In these the trigone is always involved, often so much so as to make the finding of the ureters a matter of great difficulty in well-marked cases. The ureteric ridges are indistinguishable from the heavy trabecular branches, and the ureteral orifice lies buried between them, its location being determined only by the jet of urine. In such cases the fundus and sides may also be involved, but the picture is very different. In tabetic bladders with well-developed trabeculation, the cystoscopic picture may resemble closely that of mechanical obstruction, making diagnosis by inspection a matter of greater uncertainty. It will be seen from this that the topographical arrangement of the trabeculæ is of great importance, and the earlier the case is seen the greater is its value.

In my cases the distribution of the trabeculæ was as follows:

	Cases.
Fundus and side walls alone,	9
Generally distributed,	9
Trigone and side walls alone,	2
Trigone alone,	2

In 3 cases no trabeculation was present.

In the latter the absence of urinary symptoms, residual urine, and infection did not obtain as might be supposed. Each was noted in 2 cases.

To return for a moment to the three cases presenting no urinary symptoms, it was found that trabeculation was present in two of these. It was also observed in all of the five cases without residual urine. In other words, organic bladder changes had occurred before the loss of vesical compensation, of which residual urine may be considered an important indicator.

The character of the trabeculæ is of nearly as great diagnostic value as their distribution. In the early cases especially, but, generally speaking, in all, the trabeculæ are seen to be delicate and regularly branched. Except in cases of long standing, the interspaces are shallow, "saucer-shaped" (Walker), without the tendency to develop deep, narrow-mouthed pockets.

In contrast to these we see the trabeculæ of mechanical obstruction as coarse rounded cords, interlacing in every direction, their interspaces deep and pouching, in some instances forming true diverticulæ by evagination of the bladder wall.

The accompanying photographs show this difference in the character of the trabeculæ fairly well. Fig. 1 is from a case of post-diphtheritic paralysis of the bladder of twenty years' duration, where, for our purposes, the symptoms were the same as those in tabes. Fig. 2 shows the trabeculæ in a bladder with prostatic obstruction. It will be seen that the difference in the appearance of the two is quite marked.

Fig. 1. Post-diphtheritic paralysis of the bladder of twenty years' duration. Trabeculæ quite similar to those of tabes, delicate, regular, without tendency to diverticulation. Photograph by L. S. Brown.

How, now, shall we explain the trabeculation of the bladder in tabes? Let me say at the outset that no theory is at hand, so far as I know, to solve the riddle of the difference in distribution of trabeculæ in the two types of vesical obstruction. All we know is that this difference exists, that it is of great diagnostic value, and that in a few cases of tabes the topographical arrangement is identical with that of mechanical obstruction. On the other hand, I have never seen a mechanically obstructed bladder with trabeculation distributed as it in tabes.

Secondly, what are these trabeculæ, and what difference, if any, exists in the two types mentioned? Are they evidences of true hypertrophy of the detrusor muscle, or are they signs of an atrophy of interstitial tissue or of the bladder musculature itself? If atrophy is going on in either tissue, is it due to pressure, to a trophic disturbance, or to infection?

In the first place, there is a difference in the two kinds of trabeculæ. This has already been

described. It is fair to say, however, that it is not invariable. In a number of my cases the appearances were such that no one could say whether he was looking at a tabetic bladder or at one obstructed by a prostate, for example. This similarity occurred quite as often in patients with little or no disturbance of urination as in those with marked symptoms.

The same remark about the appearances of the trabeculæ applies to their distribution. Those of tabes may occasionally resemble those of obstruction, but the opposite does not obtain so far as my experience goes.

Whether trabeculæ are the result of atrophy or hypertrophy is a question of many sides. If they are due to atrophy of muscle, connective tissue, or both, from trophic disturbances, why do they occur in obstruction of mechanical origin where no nerve lesion exists? An answer to this question would eliminate much of our difficulty.

FIG. 2. Bladder mechanically obstructed by hypertrophy of prostate. Trabeculæ coarse, interspaces deep, forming little diverticulæ. This and the preceding photograph do not illustrate satisfactorily the different types of trabeculæ as seen with the cystoscope. However, in the absence of good cystoscopic photographs, I venture to offer these to illustrate my point. Photograph by L. S. Brown.

If the atrophy is due to pressure, why is it seen in cases where the intravesical pressure is so little above the normal that there are no urinary symptoms whatever and no residual urine? The latter and the symptom of difficult micturition are generally accepted as the indicators of increased pressure within the bladder brought on by an obstruction to urination. None the less, trabeculæ are seen before either of these. I think the consideration of this point in my second article will clear up this question.

Finally, is the trabeculation a result of detrusor hypertrophy? I think it is, at least in the early stages. My own observations, as well as those of Hirt, Böhme, Birch-Hirschfeld, Kaufmann, Ehrlich and Brieger, Hallé and Motz, Cealic and Strominger, and Posner substantiate this view. The very fact that it occurs before any sign or other symptom of bladder disturbance shows that the detrusor has been doing extra work. This extra effort is such that sooner or later the patient has to call on the pressure of his abdominal muscles to aid him in the emptying of his bladder. An explanation of this extra effort will be forthcoming.

Hirt has suggested that the question might be of thickening of the bladder wall as a result of overgrowth of connective tissue, seen in cases of chronic cystitis. This was discussed in the cases reported by Cealic and Strominger. If trabeculæ are due to this, how can they be accounted for in bladders where no inflammation exists? My observations agree with those of Nitze and the more recent cystoscopists, that trabeculation is very often seen without cystitis.

But the question is not answered. It is really a matter of primary detrusor hypertrophy due to the extra work it is called on to perform. This has been admirably worked out by Hallé and Motz in their memoir on the pathological anatomy of the bladder in chronic cystitis. These authors regard the detrusor changes as occurring in three stages. First, a pure hypertrophy, often tremendous, of the bladder muscle, and recognized as trabeculation. Secondly, an infiltration of connective tissue involving not only the interstices of the muscle layers, but also those of the muscle bundles themselves. Finally, the atrophic stage sets in and here the muscle bundles are infiltrated and replaced by connective tissue until they are seen at last only as little islands of muscle. These observations were later verified by those of Cealic and Strominger.

It seems to me, therefore, that we have here the explanation of the findings in tabetic bladders. At first hypertrophy, pure and simple, of the detrusor. Next, the occurrence of residual urine which invites infection, making it a matter of cystitis plus obstruction. The remaining steps are like those already described.

As a concluding remark, I may say that further investigation of bladders, with and without mechanical obstruction, especially if taken in their earliest stages, may show us that the trabeculæ are not so different, after all, in either character or distribution.

A summary of the results of this investigation shows that,

1. Trabeculation of the bladder in tabes is found in more than 80% of cases, and may occur before any symptom or other sign of vesical disturbance.

2. In tabetic bladders it is found in the fundus and side walls only, in typical cases. It is more delicate and regular than that seen with mechanical obstruction.

3. It is probable that it is due to a primary detrusor hypertrophy.

4. Residual urine is found in more than 70% of cases, often before any symptoms begin.

5. In over 50% of all cases the urine is infected.

6. Cystoscopy is generally a painless procedure, a fact which is of some diagnostic value.

7. Urinary disturbances, variable in character, are observed in over 90% of all patients with tabes.

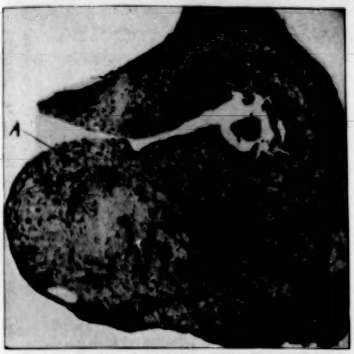

FIG. 1. Section of appendix. x3½. The small black areas, especially at the left, *A*, are clusters of ova.

FIG. 2. Section of appendix showing masses of ova surrounded by connective tissue. x125.

FIG. 3. Low power of urinary sediment, showing blood, pus, crystals and ova. In upper right-hand corner is miracidium that has just hatched out, leaving the empty shell behind it (to left). x200.

BILHARZIASIS; REPORT OF A CASE WITH APPENDICITIS; LITERATURE SINCE 1904.

BY C. GUY LANE, M.D., WOBURN, MASS.

Cases of bilharzia hematobia are sufficiently rare as yet in the United States to warrant being recorded, especially if they present features not found in those cases thus far reported. The following case is interesting in that it shows infection of both the genito-urinary and intestinal tracts, and also in the fact that microscopical sections from the greatly thickened acute appendix, which was obtained at operation, show terminal spined ova of the parasite scattered about in the wall of the appendix, these eggs being probably the predisposing factor in the attack of acute appendicitis. Appendices similarly affected have been reported in England and in Africa, but none in this country so far as I have been able to find out.

The case is as follows:

T. P., twenty-two years old, single, born in Ireland, a laborer, was admitted to the Worcester City Hospital on the night of Sept. 4–5, 1908, with the history of a sudden sharp pain in the right lower abdomen three days before. He had vomited frequently, had had "chills and fever," headache, and complained of tenderness over the painful area. His bowels had not moved for two days. His symptoms had increased in severity, and he was seen by his physician and sent to the hospital at 11 P.M. on the 4th. Examination showed a well-developed and nourished young man, with good color, and evidently in some pain. The heart and lungs were negative. His pulse was regular, rapid and rather high tension. The abdomen showed considerable tenderness and spasm about McBurney's point and below toward the median line. There was no distention. No masses were felt. The liver dullness was normal. The spleen was not felt. The patient was lying in bed with his knees drawn up. The knee-jerks were present and equal. There was no ankle clonus or Babinski. Temperature, 101. Pulse, 112. White count, 23,300. The diagnosis of acute appendicitis was made and the patient prepared for immediate operation.

Operation. — Dr. G. H. Hill. Gas-ether.

A three-inch incision was made at the outer border of the right rectus. The appendix was easily located, but very adherent and extending down deep into the pelvis. It was removed with difficulty by first ligating the proximal end and dissecting downwards and tieing off the mesentery and bleeding points. The appendix was very large, about 5 inches long and fully 1½ inches thick, red, indurated and covered with exudate. A small adhesion shaped like a small appendix and about 2 inches long, extending from middle of appendix backward to gut, was tied off and cut. There was some oozing of serum but no pus was found. A cigarette drain and one piece of iodoform were left in. The peritoneum was approximated with catgut. The abdominal wall was closed in layers with catgut, and the skin with silkworm gut. There was a good recovery from the ether.

The next morning, in the course of the routine examination of the urine, which was high colored, alkaline in reaction, 1.022 specific gravity, with a slight trace of albumen and a sediment containing many leucocytes and normal red blood cells but no casts, I saw numerous large, oval, brownish bodies, with a sharp spine at one end, and a distinct smooth outer covering or shell, inside of which in many cases there seemed to be something moving about. (See Fig. 3.) I thought that these were ova of some parasite, and, referring to books in the library, I found that they corresponded to pictures and descriptions of the ova of bilharzia hematobia. The appearance of the parasite in this part of the world aroused my interest, and, on questioning the patient later, I obtained the following history, somewhat indefinite, as the events had occurred seven years before:

He had never been sick before going to South Africa with the English army in May, 1901. In August, 1901, he had "enteric fever," i. e., he was sick for about two months, but up and about, had diarrhea, sometimes bloody, with fever, no particular pain, and no vomiting. Two months or more later he began to have slight pain in his bladder and urethra at the beginning of micturition, and passed a little blood nearly every time he urinated. In the middle of 1902 he had another attack of "enteric fever," similar to the first, which lasted two or three months. He was in Africa four years and four months, and was sent home with several other soldiers with the same disease to the Army Hospital, Natali, Kent, England. He was treated there three months. The diagnosis was bilharziasis (?). He was discharged from the army as unfit for service, but was told that his prognosis would be good if he remained away from the tropics. Since then he has never been entirely free from painful micturition and slight hematuria. Occasionally there has been no blood at all, but there is usually just a little at the end of micturition. His general health has been good until his present illness.

After the operation the patient was in poor condition for forty-eight hours, and it was thought that he had general peritonitis. Stimulation, irrigation of lower bowel, enemas and poultices relieved the distention and pain. The cigarette drain and wick were removed on the 8th, three days after operation, and considerable pus came from the wound. This discharge continued and the wick was replaced every day up to Oct. 8. Examination of the pus showed B. coli communis. The patient vomited more or less up to the 15th, with occasional pains in abdomen. The stitches were taken out on the 14th, and the wound was still discharging considerable pus. The patient meanwhile was having some pain on micturition and passing only a small amount of smoky urine at a time. He had urotropin and potassium citrate with practically no relief. He was out of bed on Oct. 4 and was discharged on the 20th to the Out-Patient Department. He returned there

at intervals for three weeks, when the wound was entirely healed. He had considerable tenderness about the scar, especially on the upper and inner side, where there was considerable induration. He also complained of occasional shooting pains through the abdomen. The hematuria and painful micturition had persisted in about the same degree.

On Dec. 11 he was sent into the hospital with the diagnosis of intestinal obstruction (?). He had been at work from Nov. 30 until Dec. 9. On the 8th he had had "gas on stomach" and some slight pain, and on the 9th had vomited twice, with increase in pain and tenderness, especially in the epigastrium. His bowels were constipated. (He did not know when the last dejection occurred.) Examination showed that there was considerable muscular spasm and tenderness in the right epigastrium, but no distention, and no masses were felt. He was given salts and kept quiet in bed, with morphia for pain. His symptoms disappeared and he was discharged on the 14th.

I have seen him at intervals since he was discharged from the hospital, the last time on Sept. 18, 1910. He has been steadily at work in the loom works, and later in a tannery, with only an occasional pain in the abdomen. The frequent micturition has persisted and is usually painful and urgent. The urine usually has a little blood, especially in the last portion, and numerous ova can be found in the sediment. He looks to be in first-rate condition.

While he was in the hospital every specimen of urine examined contained the ova with pus, blood and albumen, and the stools also showed the ova and miracidia. In the stool the miracidia were first observed swimming about, and after a search the empty shells and ova were found. The vomitus on the 14th was dark green and thick, almost fecal in character, but no ova or blood were found in it. The white count on the 10th was 12,400 and the differential was as follows: Polynuclears, 78%; lymphocytes, 15%, and eosinophiles, 7%. On the 15th, when he was feeling a little worse and his temperature was elevated slightly, the white count was 21,700 and the differential count showed, polynuclears, 92%; lymphocytes, 5%, and eosinophiles, 3%.

The specimen removed at operation was a large, dark-red appendix, covered with a fibrinous exudate, with a marked thickening and induration of the wall, especially on one side, where it was nearly an inch thick. The lumen was filled with a thin, foul, dirty brown detritus, and no concretions were found. The thickening of the wall was due to a marked increase in the connective tissue, which in many places was arranged in whorls, in the center of which were numerous ova. These ova were scattered all through the tissue singly and in groups, and all the spines which were visible were terminal. Many polynuclear leucocytes were seen scattered about in the tissue as seen in an ordinary acute appendicitis; there was considerable congestion, especially of the mucosa. (See Figs. 1 and 2.)

The ova never hatched out in normal urine as far as I could observe, but in a liquid stool I saw the miracidia swimming about (see Fig. 5), and in the urine on the addition of water and warmth they broke out even as late as forty-eight hours after the urine was voided. They did not live long at room temperature or in the incubator or in bouillon, nor has any attempt to follow their life history further been successful. All the eggs observed showed terminal spines, even those seen in the stool.

It was suggested that guinea pigs be used in order to develop the miracidia if possible. Into one the unhatched ova were injected intraperitoneally and also into the abdominal subcutaneous tissue. Into a second pig the miracidia hatched from the eggs were injected in the same way, while the third pig was put into a separate cage and fed with carrots, on which both the ova and the miracidia were placed. The first pig died three days later, apparently from a localized peritonitis. At the autopsy, no trace was found of the subcutaneous injection, but in a small piece of tissue, apparently a lymph node, from the under surface of the liver, were several ova in which the miracidia could be seen to be moving about. No other evidences of ova were found. The other two pigs were killed two months later, and autopsies, including examination of the urine found in the bladder, showed no signs of the ova.

REVIEW OF CASES.

In connection with this case it has seemed well to mention the other cases reported in this country and to look over the literature since Dr. O'Neil's very complete paper in 1904.

The first case was reported in 1882 by Dr. Booth, of Sparta, Ill., who found eggs with spines in the urine along with ciliated embryos and mature worms. The presence of the mature worms would throw some doubt on the diagnosis, as it is not known that they appear in the urine. The description of the ova is rather meager and there are no pictures or drawings as confirmatory evidence, so that there seems to exist a reasonable doubt as to the diagnosis in this case.

In the second case, reported by Dr. Curtis, of New York, in 1896, all the evidence lies in the fact that in the report of the case, the diagnosis of bilharzia was made on the microscopical examination of a bladder tumor that was removed at operation. There was no mention of any ova in the urine.

The third case was reported by Dr. Brooks, of New York, in 1897. It was a patient sent to him by Dr. Edebohls, and in the urine he found the eggs and watched them hatch out. The case was demonstrated at a clinic by Dr. Porter as the first one in this country. It was later studied and reported by Sondern working under A. Jacobi. This seems to be the first bona-fide case in which the diagnosis can be made from the description or pictures in the report of the case.

In 1900 Dr. Walker, of Evansville, Ind., reported a case, a woman who had a tumor connected with her bladder, and from this was taken a fluid in which ova, embryos and worms were found. The case was reported by the Raffertys later, in 1904, but the presence of the worms, and the pictures, tend to class this case among the doubtful ones.

Dr. Pool, of New York, in 1903, reported another case, in which the ova were found and photographed, and the process of hatching out studied. This case is probably the one referred to by Rankin in the *Brooklyn Medical Journal* in 1904.

Later in 1904 O'Neil, of Boston, reported a case with some excellent drawings and a review of the literature of bilharziasis. Since that time I have found reports of five other cases, aside from those reported among the Boers at the World's Fair at St. Louis in 1904. In regard to these latter cases, the urines of 45 of the 300

Boer soldiers and South African negroes were examined by Dr. Smith, of Atlanta, and in 7 were found the ova of bilharzia. None had any symptoms, but all gave a history of earlier symptoms. He also observed only terminal spines on the ova.

In 1905 Anders and Callahan, of Philadelphia, exhibited a man who was in Africa for two years ten months about nine or ten years previous. He complained of persistent hematuria, and the ova were found in his urine, the ova showing the terminal spines.

One year later Gunn, in San Francisco, reported 2 cases of the intestinal variety, apparently arising in Porto Rico. Eosinophilia was present, but this might have been accounted for by the other parasites found in the stools. The ova in these cases had lateral spines, and no motility was observed, even upon rupturing the shells. Gunn also mentions another case not reported, under the care of Dr. Lando, U. S. N., at the Mare Island Navy Yard Hospital. The patient had been in Africa and was suffering from the urinary form of the disease.

Robbins, of Detroit, in 1907, reported a case seen in 1904, a man who had served in the British Army in South Africa. He appeared with hematuria, frequent micturition and pain over the bladder, and his urine showed "regular ovoid bodies, yellowish in color, with a marked projecting point at one end." He made notes on the case but did not know what ova they were, until eight or nine months later, when he saw the drawings and the records of the cases reported by Dr. Smith, of Atlanta, and then realized that his own case was similar, and reported it.

Summing up this list of cases, it is seen that those reported by Brooks, Pool, O'Neil, Anders and Callahan, and Robbins, aside from those found by Smith, of Atlanta, are undoubtedly bilharzia hematobia. In those reported by Booth and Walker, the facts do not coincide with what is now known about this parasite. The case as recorded by Dr. Curtis, in the Proceedings of the New York Pathological Society, produces no evidence to confirm the diagnosis. The same might be said about the case at the Mare Island Navy Yard, as mentioned by Gunn, while Gunn's two cases may be classed as another variety of the bilharzia, especially in view of the reports from recent investigations in Porto Rico.

REVIEW OF LITERATURE.

In the literature since 1904 the method of infection or the mode of entrance into the body has been studied more than any other phase of bilharziasis with a view to better prevention of the disease if possible. But the question has not been definitely settled, although Looss thinks that the theory of infection through the skin gives the best explanation of the facts known. This includes also the discussion of the probability of an intermediate host. If there is one, it is not a rare creature, as the disease is so widely spread in South Africa, and is appearing in other parts of the world, the more so since the soldiers returning from the Boer War with it have scattered about so much. It was thought that the molluscs might be the host as they are in the case of other trematodes, but all the common molluscs have been searched without a trace of the bilharzia, and endeavors to provide a temporary shelter for the ova have not been successful. (Sandwith.) Any theory in regard to the method of infection must account for the passage of the ova from man to moisture, for water seems necessary for the hatching of the ova and the passage of the miracidia from water to man, and also must consider the habits of the host and the biological characteristics of the parasite. That is, the infected stool or urine must come in contact with water within forty-eight hours, and after that, the miracidia must find the host within thirty to forty hours, at least.

The theory of infection by mouth seems impossible as the miracidia cannot live in 1-1000 HCl more than one minute, or three minutes in 1-2000 HCl (Sandwith). And miracidia introduced into the stomachs of monkeys and other animals die at once. Then, too, the Greeks and Europeans in infected towns eating the same fruits and vegetables and drinking the same water are less often infected than the natives (Looss). So that the stomach does not seem to be the only mode of entrance. Elgood, however, from the investigation of the girls of the middle class schools in Cairo and the female patients in the hospital, and a study of the water supply, does think that infection is possibly due to faulty storage of drinking water or eating raw vegetables and fruit washed in dirty canals or water, and probably not due to bathing. Looss, in his article, takes up in detail Elgood's paper, and claims that her facts favor the skin infection theory, and brings out additional evidence in its favor.

Infection by the urethra is not believed in by Looss for general parasitological reasons. Sandwith gives as argument the fact that among married couples the infected person has not been known to have infected the other party. Allen found a man among the Indian attendants at the hospital where he was, who was willing to undergo a test. On three occasions he injected into his bladder many eggs of the parasite containing vigorous embryos and satisfied himself that he retained these eggs for several hours, but the result was absolutely negative. He was at the hospital for several years afterward and left free from the parasite. But Allen does think that excellent protection for the embryo, which gets in while bathing, is afforded by a long foreskin, which guides it to the urethra, and to the membranous part, from which he thinks that it extends upward, judging from the extension of the symptoms, and as a preventive he recommends circumcision.

Looss also rules out infection by the rectum as utterly improbable on general grounds, without explaining what these grounds are, and thinks that infection through the skin explains all the facts, especially since it is known that uncinariasis

gains an entrance to the body by this means. The distribution of the disease seems to bear it out, for children in towns and the adult male laborers in the country are the chief sufferers (Looss). The latter class work bare-legged for hours in moist or muddy ground and thus are infected and reinfected. The children are playing together on moist ground or in muddy pools or ponds, and if one child is discharging ova there is a chance for many others to get the disease (Looss and Sandwith). Also the disease is rare in females, except little girls and peasant women who work barelegged on flooded plowed land. If the skin is the means of infection, it is easily seen that persons bathing with or near infected persons, or in recently contaminated water, are subject to infection.

Burfield mentioned another method of infection in a man from South Africa with an appendiceal abcess which had pointed posteriorly through the sciatic notch and was opened there. Later in England the appendix was removed and found to contain many bilharzia ova in its wall. The man had frequently bathed in the river after the sinus had formed, and Burfield thought that the bilharzia had entered there rather than that the appendicitis was caused by the bilharzia.

Various opinions have been expressed in regard to the significance of the lateral and terminal spines on the ova. Sandwith says that eggs passed in the urine generally have terminal spines and those in the feces often lateral spines partly because of the pressure of the feces. There are not two varieties of worms, and it is not necessarily true that terminal spined ova come from the bladder, or that lateral spined ova are peculiar to the rectum. He believes that all normal eggs have terminal spines and that eggs with lateral spines are abnormal or abortive. The same immaturity is found in other trematodes, according to Looss. Since 1906 many cases have been reported from Porto Rico and the Canal Zone and cases that have been in Porto Rico, in which lateral spined ova have been found, and it has been suggested by Manson, in 1905, that these lateral spined ova belong to a different member of the bilharzia family, and evidence accumulated by Holcomb, Higgins, Gonzalez-Martinez and other workers, in Porto Rico, tends to favor this view. The cases reported by Gunn seem to belong to this class.

These are the principal points brought out in the last five years, but additional data are necessary to settle definitely the questions in regard to the life history of the parasite, and thus the rational means of prophylaxis and treatment.

SUMMARY.

1. This is a case of both intestinal and genito-urinary bilharziasis with terminal spines on all the ova seen;

2. Complicated with an acute appendicitis, with operation and recovery, sections of the appendix showing many bilharzia ova in the wall.

3. A review of the reported cases brings out the fact that there are only five undoubted cases of the South African bilharzia hematobia among them.

4. In the last five years, more evidence has been advanced for the skin infection theory.

5. Investigation shows that the lateral spined ova may belong to one species of bilharzia and the terminal spined to another.

I am indebted to Dr. C. D. Wheeler and Dr. G. H. Hill, of the Worcester City Hospital, on whose service the case was admitted, for the privilege of reporting this case, and to Dr. C. L. Overlander, of Boston, for help and suggestions and also for the pictures. The photographs were taken by Mr. L. S. Brown, in the Pathological Laboratory of the Massachusetts General Hospital.

TUBERCULOSIS AMONGST THE PHILIPPINE SCOUTS (NATIVE TROOPS) OF THE UNITED STATES ARMY.

BY ISAAC W. BREWER, M.D.,
First Lieutenant Medical Reserve Corps, United States Army.

TUBERCULOSIS, although causing the largest mortality, has probably received less attention than any other disease that afflicts the inhabitants of the Philippine Islands. In the city of Manila it causes about 14% of the deaths, and the death-rate is 538 per hundred thousand. Just how much sickness it causes amongst the native population is difficult to ascertain from the data available. However, some information upon the subject may be had from a study of the records of the United States Army, from which it is possible to obtain the admissions to "Sick Report" because of tuberculosis amongst the native troops for the years from 1902 to 1908.

As a military force, the Philippine Scouts were organized in the summer and fall of 1901, and the number has been increased from time to time until there are now about 5,700 on the rolls. They are organized into companies of one hundred and ten men each, and in most instances four companies are assembled into a battalion.

When first organized, these troops were in the field much of the time, and were for the most part quartered in native towns, occupying the houses vacated by the inhabitants. Later it became the policy to construct barracks of native material outside of the towns for their use. However, from the very first, great attention has been paid to the sanitation of their quarters and the surrounding grounds.

Before enlistment each man is required to pass a rigid physical examination, and only men in the best physical condition are taken into the Scouts.

The clothing issued to them is about the same as that used by the white soldiers, and is generally considered as satisfactory.

Since July 1, 1910, they have been allowed thirteen cents per day for subsistence. Previous to that time they were issued a daily ration as follows:

	Ounces.
Fresh beef,	12
Flour,	8
Rice,	20
Potatoes,	8
Coffee,	1
Sugar,	2

If available, the company commander could substitute bacon, canned beef or fresh or canned fish for the beef allowance, and at times onions and canned tomatoes were issued in lieu of part of the vegetable allowance. At all times the diet was varied and enlarged by articles purchased from funds obtained from the post exchange and other sources.

Beri-beri prevailed extensively amongst the native troops for some years, and early in the present year, mongos peas were substituted for a portion of the rice ration. This substitute is now largely used, and beri-beri has disappeared from amongst the Scouts.

As regards the nutritive value of the native soldiers' ration, Dr. Hans Aron, of the Philippine Medical School, who has made a study of the diet of the Filipino, informs me that the above diet represents about 3,000 calories, which is about the same as the well-to-do natives of the town of Taytay provided for themselves. The Scout ration, however, is richer in proteids, and from its greater variety is probably more readily assimilated.

These troops spend a large portion of their day in the open air, either drilling or working, and the physique of the men improves greatly during their term of service.

In general, it may be said that the native troops are well housed, clothed and fed, and are better able to resist disease, than is the civilian population of the Islands.

Amongst picked men, living an outdoor life in a mild climate like the Philippine Islands, we should expect to find but little tuberculosis; but, on the contrary, the disease is very prevalent amongst them. During the seven years ending with 1908, 211 Scouts were admitted to Sick Report because of tuberculosis, which gives an average admission rate of 6.3 per thousand. This is about one per thousand greater than the rate for the white troops serving in the Philippines, and is nearly twice as great as the rate for the native troops in India.

	Admission rate.
Native troops, Philippines,	6.3
Native troops, India,	3.6

These differences are certainly worthy of careful consideration by those who are responsible for the health of the Scouts.

It is believed that most of the cases of tuberculosis amongst the Scouts are contracted in the "soldiers' barrio," which is located on the outskirts of most of the posts. Nearly every Scout is either married or lives with a native woman. It is the custom to allow the men, when not on duty or "restrictions," to sleep out of barracks. In most instances, the company commander assures himself that the houses occupied by the families of his men are reasonably clean before he will allow them to sleep out, but these buildings are nearly always deficient in ventilation, especially during the night; and as most of the houses in the Philippine Islands harbor a consumptive, it is safe to assume that nearly all of the homes of the Scouts are infected with tubercle bacilli.

A great step towards the prevention of tuberculosis amongst our native troops would be to move "soldiers' barrio" on to the reservation so that it may be under military control. It would then be possible to see that the houses are properly ventilated, and to guard against the introduction of cholera and similar diseases. If this cannot be done, much good can be accomplished by making frequent inspections and restricting those men whose families do not comply with the sanitary regulations. Under no circumstances should the barrio be abolished, or any restrictions placed upon the marrying of the Scouts, because it keeps them free from venereal diseases which prevail most extensively amongst the white troops.

At present, persons who contract tuberculosis in the Philippine Islands have but little chance of being cured. Modern treatment of the disease is practically unknown, excepting in Manila, where there are a few clinics, and where a sanitarium has just been started. Hospital facilities for advanced cases can rarely be secured even in Manila.

Americans who contract the disease are, for the most part, returned to the United States. The native soldiers are collected at the division hospital and discharged within a few months after the diagnosis of tuberculosis is made. A large portion of the native population receive no treatment, excepting patent medicines, of which there is an unlimited supply in the Islands.

It will be a long time before the Philippine government can do much towards the prevention of this disease. In the meantime, any Americans who are interested in the Philippine Islands can make no better investment than to establish a clinic or hospital for the treatment of tubercu-

losis in some of the provincial towns. The statistics here presented show that a minimum of not less than six beds per thousand will be required. This can hardly be hoped for, but any endowment will be gladly received by those who are working to eradicate tuberculosis from the Philippines. The Philippine Islands Anti-Tuberculosis Society has recently been organized and is making a start towards the suppression of tuberculosis, but it needs all the encouragement and financial assistance that can be had from the people of the United States.

Clinical Department.

NEW ENGLAND BRANCH OF THE AMERICAN UROLOGICAL ASSOCIATION.

SPRING MEETING HELD AT THE BOSTON MEDICAL LIBRARY, MAY 24, 1910.

President, DR. F. S. WATSON, Boston.
Secretary, DR. R. F. O'NEIL, Boston.

DEMONSTRATION OF PATIENTS.

DR. F. S. WATSON, of Boston, showed a patient who has had

A PERMANENT LUMBAR RENAL FISTULA ON THE LEFT SIDE FOR NEARLY SIXTEEN YEARS. BILATERAL RENAL FISTULA FOR THE LAST SEVEN YEARS, AND WHO HAS BEEN ALL THE WHILE, WELL, COMFORTABLE AND ACTIVELY EMPLOYED.

I have already, some years ago, reported this case. My reasons for doing so again are as follows: (1) In 1905 I proposed a new method of attacking certain cases of vesical tumor, and the essential feature of that proposition was the establishment of bilateral permanent lumbar renal fistulæ. (2) A distinguished member of the American Association of Genito-Urinary Surgeons made the statement at its recent meeting in Washington that death would be preferable to enduring the miseries entailed by the existence of permanent lumbar renal fistula. (3) The fact that this statement is far from being true provided the attending surgeon knows how to arrange the renal drainage properly. (4) The further fact that I have a patient to show to you here to-night who has had to endure the "miseries" of renal fistula in one loin for fifteen years and in both loins for the last seven of them, and whose case offers the most positive contradiction to the statement made by my distinguished colleague which I have quoted above.

This patient, who will presently tell you what his experience has been, I have had under observation for nearly sixteen years. He has been leading an active business life all the while, he has been well, free from pain and even discomfort, and no one has been aware of his infirmity.

The whole question of misery or the reverse in the case of a patient with permanent lumbar renal fistula depends upon the attending surgeon's ability or inability to arrange the drainage of the urine in such a way that the patient and his clothing shall be kept dry and absolutely free from all contamination with the urine, which, in many instances, runs around the outside of the drainage tube as well as through it (and this is the most essential point in the matter); furthermore, that he shall be able to take part in life actively and that he shall be free from all pain and discomfort of consequence. Now these conditions cannot be secured in the case of a day laborer, but they can be secured in that of any one in ordinarily good circumstances and who can be properly cared for. In some cases it is not a question of choice with regard to the establishment of a permanent renal fistula, and in such instances it is most important to know how to care for the patients.

The bare statement of the steps that were taken successively in this case is all that is necessary for the purpose of this communication.

Fifteen and a half years ago, pyonephrosis of the left kidney and an obstructed ureter. *Nephrostomy* and the establishment of a *permanent lumbar renal fistula* with a large rubber drainage tube continuously worn in it.

Nine years later, acute *infection of the right kidney*. The *same operation upon it* as was done on the left side, and permanent drainage established in that loin.

Four years later, calculi formed in both kidneys. Calculi removed through the fistulæ after they had been incised and enlarged. An interval of about one month between the operations. Drainage resumed. *Just before the second of these two operations*, a *severe hemorrhage*, which was arrested by ligature of a vessel at the inner end of the fistula leading into the left kidney. Calculus removed at same time.

Three years later, chill, fever, *due to pus formation* in the right kidney, spontaneous evacuation of the pus through the bladder. Recovery.

These points sum up this patient's experience in the matter of operations, of which there were in all five. The whole length of time demanded for convalescence from these five operations during the fifteen and a half years has been about seven months. Throughout the rest of these years the patient has been actively employed, well and free from all discomfort other than that entailed by the fact of being obliged to wear his receptacles for the urine on his back, and the time required in order to wash out the kidneys daily.

This is the point to which I wish to direct your attention, and it was for the sake of giving you all here to-night the actual visual proof of this patient's condition, and of hearing from his own lips just how much or how little distress he has had from his infirmity, that I have again reported this case. I will now ask him his own view of the conditions under which he has lived all these years. "Wont you tell us, Mr. ——, just what your experience with this condition has been?"

Mr. —— replied that there was really no actual discomfort in the condition. That apart from its taking the time required for the daily washing out of the kidneys morning and night, and the adjusting of the tubes, it entailed not much more trouble than shaving oneself daily. He had been wholly free from pain and even discomfort of any consequence. Perhaps the greatest inconvenience attaching to the condition was the fact that he was prevented from making visits in the homes of friends, but otherwise he had not been handicapped by it in any way, nor was any one aware

of his infirmity except a few medical men and the members of his family.

He had been in active business with the exception of the short periods when he was kept away on account of the different operations, which was, as Dr. Watson had said, about seven months in the course of the fifteen odd years that had passed since the first operation. He had always been able to take all the exercise he needed, and had recently been for a short time in the country, where he had been taking daily walks of eight or ten miles. On the whole, he would say that he thought he had had as little discomfort, so far as the constant drainage from the kidneys is concerned, as the average man has from the various minor ailments which he is likely to have to endure.

In conclusion, gentlemen, I think I may say that you will agree with me, after what you have seen and heard here to-night, that the statement I quoted at the beginning of this communication, to the effect that death would be preferable to enduring the miseries imposed by permanent lumbar renal fistula, is very far from being justified, and I believe that you will join me in contradicting it positively if you should hear it made in the future. I should add that the apparatus which I have some years ago devised for the purpose of keeping the patient and his clothing dry and for receiving the urine that flows either through or around the tube has not been required in this instance because of the fact that there is no leakage around the tubes at all owing to the close adaptation of the tract of the fistula upon the outside of the drains. This fortunate feature makes it perfectly simple to prevent all contamination of the skin or clothing by the urine. In many cases, however, a special device is demanded in order to avoid this, the one really distressing feature of such renal drainage, and the apparatus which I devised for this purpose is entirely satisfactory for such patients. I have already published descriptions of it so I will not take more time now to demonstrate it to you. The descriptions will be found in Watson and Cunningham's "Diseases and Surgery of the Genito-Urinary System," 1908, Vol. 2, chapter on Operations on the Kidneys. It is described but badly illustrated in the *Annals of Surgery*, September, 1907. The apparatus is made by Messrs Codman & Shurtleff, instrument makers, Boston.

Question. What arrangements are made at night?

Answer. He takes off the can, removes the tubes, putting in long ones which go to bottles outside the bed.

Demonstration of Specimens.

Dr. J. W. Keefe, of Providence, showed a specimen of

SARCOMA OF THE KIDNEY.

I have here a specimen supposed to be the right kidney which I removed a short time ago from a woman forty-four years of age. Upon incising the kidney I found several calculi which may be seen imbedded in the specimen. The patient stated that some twelve years ago she had a severe cystitis and was treated at the time, in a hospital, by bladder irrigation.

She remained fairly well until three years ago, when she commenced to have pain in the back and right loin and at present a mass can be felt in the right side just below the costal border. She complains of frequent micturition, more particularly at night. She has been

Fig. 1. Median section. Sarcoma of kidney.

unwell but twice during the past year and has lost about twenty pounds in weight.

Fig. 2. (x150.) Sarcoma of kidney.

I made a cystoscopic examination on the day of operation and saw practically normal urine issuing

Fig. 3. (x300.) Sarcoma of kidney.

from the left ureter. No fluid issued from the right ureter.

The specimen here presented, which appeared to be the right kidney, was removed by the transperitoneal operation. I encountered very little hemorrhage. The renal artery and vein could not be demonstrated. Upon incising the specimen I could see no evidence of renal tissue, but found several calculi imbedded in the mass.

The pathologist at the hospital reported that the specimen was a small round-celled sarcoma. Subsequently I asked Dr. Harold G. Palmer, of Providence, to examine the specimen and his report is as follows:

PATH. No. 2021.

SPECIMEN FROM Kidney. RECEIVED June 4, 1910.
CLINICAL DIAGNOSIS ?
PATHOLOGICAL DIAGNOSIS. Tumor—embryonal in type.

The specimen received is a tumor that includes the right kidney and its perirenal fat. The specimen has been bisected and preserved in formalin solution. The fresh specimen is reported to have had the appearance, on section, of a uterine fibroid. The outside measurements are: Circumference, perpendicular, 35 cm.; transverse, 31 cm.; a somewhat flattened ovoidal mass. The outer surface consists of irregularly lobulated shining yellow fat. No capsule can be demonstrated. The cut surface presents an irregular stellate mass of bluish to yellowish-white dense tissue imbedded in an envelope of pale yellow fat that varies in thickness from 1 to 4 cm. The entire cut surface measures 11 by 14 cm., the stellate mass 5 by 8 cm., and approaches nearest to the surface at the anatomic level of the hilum, where it appears prolonged as fibrous bands into the fat. A calculus, the visible portion of which measures 12 by 25 mm., projecting 14 mm. from the cut surface, is situated in a position that corresponds with the renal pelvis and is closely surrounded by a dense envelope of cartilaginous consistency. This calculus terminates in a rounded point that fits into a facet on a small calculus that is imbedded in the substance of the opposite cut surface of the specimen (Plate "A"). There are two more imbedded calculi ("B" and "C"), the points of which are barely visible. A few millimeters below these calculi there is an area ("D") which is of the consistence of cartilage and is infiltrated with calcareous matter. A cavity near the margin of the specimen measures 3.5 by 2 by 1.5 cm. Its wall is thick and firm the lining thrown into longitudinal folds. The tissue inside the fatty envelope is firm, the cut surface smooth. All normal markings are obliterated and there is nothing whatever macroscopically to suggest the presence of renal tissue. The specimen weighs 565 gm. Sections taken from various planes and regions of the specimen.

Microscopic examination. — Sections present a tissue that is exceedingly variable in component elements and complex in structure. There are at least three distinct types of cells present, viz., (1) epithelial, (2) lymphoid, (3) connective tissue, the last being present in several morphologic forms. The first two types go to make up the essential feature of the neoplasm, namely, tube-like clusters of epithelial cells indefinitely and irregularly situated in a very cellular connective tissue stroma, and more or less isolated, larger and smaller islands of lymphoid cells (Plate II). The epithelial cells are somewhat variable in size. All have fairly uniform sized round or oval nuclei that have a delicate chromatin network which stains readily. The cytoplasm is generally clear, but at times finely granular and occasionally shows minute vacuoles. The arrangement of the cells is, as already stated, in tube-like clusters. Sometimes these occur as solid masses of cells with a sharply defined, rounded outline (Plate III, A); at other times the cells are so grouped that a central or eccentric space or lumen is formed (Plate III, B). The more highly developed tubes show two or more layers of surrounding cells. Individually these epithelial clusters vary widely in size. In some instances they are sharply defined from the surrounding connective tissue, but often the definition is less distinct, the cells blending gradually into the cells of the stroma. The tissue that is considered as stroma consists of connective tissue cells that are, at times, small, compact, with small, deeply staining nuclei; at others, large, diffuse, with large, oval, vesicular nuclei and indefinite cytoplasm (Plate III). In addition to this type of connective tissue, there are numerous areas that present unstriped muscle, the amount varying from a few scattered cells to considerable bundles of crossed and interlacing fibers. The islands of lymphoid cells (Plate II) as such present nothing especially remarkable. They are never sharply defined but blend off rather gradually into the loose connective tissue. In some instances they are in fairly close association with the epithelial elements.

The specimen contains microscopic areas composed of cells that are consistent in morphology with the cells of the adrenal cortex. Scattered indefinitely through the general mass of connective tissue, there are many cells that have a bilobed, deeply staining nucleus and a moderate amount of cytoplasm rich in fine eosinophilic granules. These cells are somewhat smaller than a neutrophilic leucocyte.

This description comprises a composite picture of sections of the specimen as a whole. Individual sections show wide differences in composition, some showing chiefly lymphoid elements, others chiefly epithelial, connective tissue elements being present in both instances. The epithelium in tube-like clusters is not looked upon as degenerating tissue; it is considered a constructive process. Likewise, the islands of lymphoid cells are not considered in the light of a round-cell infiltration, but present here as aberrant lymphoid tissue.

It is difficult if not impossible to name, in a single word, the process here present. The tumor throughout is embryonal in type. Until a comparatively recent date, a large majority of tumors associated with the kidney were classified broadly as sarcomata. Recognition of hypernephroma as a distinct neoplasm caused a revision of the nomenclature. Recent studies of numerous observers have established the fact that there are new growths, malignant or benignant, that fail to come under any established classification. At present the genesis of tumors associated with the kidney is sufficiently obscure to warrant naming the morbid process present in this specimen simply as a tumor, embryonal in type.

The calculus. — Chemical analysis of one of the calculi shows the composition practically pure calcium carbonate.

HAROLD G. PALMER.

DISCUSSION (Dr. J. F. Keefe's case).

Question. Was there any fat tissues present? It looks like a lipoma.

Dr. Keefe. The pathologists reported that it is sarcoma.

Question. I would like to ask if any one has seen primary carcinoma of the kidney.

Dr. Watson. I have. It is very rare. I had one in which the growth was pure carcinoma. Secondary metastases in the kidney are very common.

Question. One point suggested by Dr. Keefe's case: In the case of malignant growths, what might be the

percentage of calculi present in these tumors? It has often occurred to me that a calculus or calculi might act in the kidney as gallstones do in the gall bladder, as the causative factor in the development of malignant disease.

Dr. Watson. In regard to the presence of calculi in malignant disease, I think they are rather conspicuous by their absence.

DR. G. O. CLARK showed a specimen of

RENAL CALCULUS.

I had hoped to present to-night a very rare specimen — what the pathologist in his preliminary report stated was *a calculus embedded in the renal substance.*

As you are well aware, the sites occupied by renal calculi are nearly always the pelvis or the calyces. Sometimes a calculus engages in the ureter and is arrested at variable points along that canal. In a certain number of cases the kidney is transformed into a series of pockets, some of which contain calculi; these pockets represent dilated calyces, and they connect with the pelvis by orifices of varying dimensions. Sometimes, secondary inflammatory adhesions obstruct the orifice previously existing between the pelvis and the calyx and the pocket is then left independent of the principal cavity of the pelvis. This possibility makes it necessary for the operator not to be satisfied with merely exploring digitally the opened pelvis and the dilated calyces leading off it, but to explore also the parenchyma of the kidney.

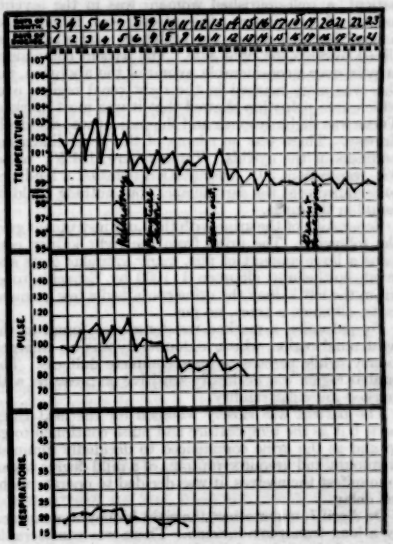
The kidney here presented by me when more carefully examined presents a calculus of smooth surface but irregular in outline, roughly the size of two peanuts fused end to end. It lies apparently in the kidney parenchyma, but in reality not so. Its sac is seen to be formed by a dilated calyx whose communication with the renal pelvis has been obliterated by inflammatory changes.

This right kidney was removed at autopsy from a woman forty years of age dying of pulmonary embolism eighty hours after perineorrhaphy done for complete tear of the perineum into the rectum resulting from high forceps delivery three weeks previous to operation.

The *accouchement forcé* was necessitated by a fibroid tumor of the anterior uterine wall. During life the kidney stone had given rise to no symptoms. The uterine tumor had been recognized. The labor had been successfully and aseptically completed.

A cystitis of B. coli origin developed post partum, ascended to the left kidney and produced a pyelonephritis.

The liver showed focal necroses and there was a septic spleen. The above autopsy findings, indicative of a colon bacteriemia, were undoubtedly predisposing causes of the pulmonary embolism which induced death. The specimens illustrating the above findings are for your inspection.



Autopsy done by S. R. Haythorn, M.D., of Harvard Medical School, Department of Pathology. Patient, Mrs. A. H., of Dr. L. F. Cusick, of Nahant, to whom I am indebted for the privilege of reporting the case.

REPORT OF CASES.

DR. C. G. CUMSTON, of Boston, reported

A CASE OF PREGNANCY COMPLICATED WITH PYELONEPHRITIS.

In the *New York Medical Journal*, 1900, I recorded my first case of pyonephrosis complicating pregnancy, since which I have published two papers, one on pyelonephritis of pregnancy and one on pyelonephritis complicating the puerperium in the *American Journal of the Medical Sciences*, respectively in January, 1906, and July, 1908. In the second paper I reported a second personal case in which nephrotomy was done with a fatal result, while in the second paper I reported three cases during the puerperium, all of which recovered. The case which I wish to report to-night has recently been under my care and is now well on the road to recovery.

Pyelonephritis of pregnancy.

Mrs. P. F., thirty-one years of age, a physician's wife, married six years. She has had two normal confinements, the first one in June, 1905, the second in October, 1907. According to her history, she has always enjoyed good health, but since her last confinement she has been troubled with varicose veins of the right leg.

Shortly after she became pregnant for the third time she began to feel tired and occasionally quite weak and dizzy, and this increased towards the fifth month to such an extent that she occasionally was obliged to remain on the lounge the greater part of the day. Ten days before coming under observation, while dressing in the morning, the patient experienced a sensation as if something had given away in the back and this was followed by quite severe pain, which, however, was less

marked towards night. The pain did not entirely disappear, but she had a fairly good night. On the next day the pain was very severe and located in the right renal region. She felt weak and complained of some headache. In the evening she had a severe chill, which was repeated twice in the night and on the next day the husband consulted with another physician. In the recumbent position the very violent pain disappeared. But there persisted a dull, dragging sensation on the right side. It was noted that the urine, which had been passed frequently during the two previous months, had been cloudy, and micturition was painful and had increased in intensity as the pregnancy advanced.

She was kept under observation for the next week, during which she ran a temperature between 101° and 102° F., more or less constantly suffering from headache as well as the persistent pain in the renal region. As the symptoms continued in spite of a milk diet and the exhibition of urinary antiseptics, she was finally sent to Boston and we were asked to see the patient in consultation.

We saw her on the morning of April 3, 1910. The patient, a well-nourished woman, was in the seventh month of pregnancy; the uterus was found three fingers' breadth above the umbilicus and slightly inclined towards the right side. The patient complained of pain over a considerable extent of the abdomen, but this was more marked in the right renal region, over which area palpation showed that it was most marked. There was slight dyspnea and the patient was decidedly drowsy. There was no edema of the lower limbs nor puffiness of the eyelids. Temperature, 101.5°; pulse, 98; respiration, 20. Auscultation revealed a loud systolic murmur at the cardiac apex, but nothing could be found in the lungs.

Separation of the urine with the Luys instrument gave the following: The urine from the right kidney contains a large amount of pus, many granular casts and much epithelium, albumen 1: 1000 by Esbach's tube. From the left kidney the urine contained a few granular casts, albumen a trace, no pus.

By palpation a marked resistence was found in the right renal region, which undoubtedly was an enlarged kidney, while percussion gave complete dullness. The lumbar region was decidedly sensitive on pressure, with marked muscular rigidity.

The patient was closely watched for the next three days, but as the temperature and pulse continued to go up and as the urine commenced to decidedly diminish in amount and uremic symptoms of a mild degree began to manifest themselves, it was decided to operate without delay.

On April 7, under ether, the right kidney was exposed by a long transverse incision. There was considerable edema of the perirenal fat, but the kidney was reached without any particular difficulty. Upon exposing the organ it was found very greatly enlarged and in its middle and at the lower pole were found two abscesses in the cortex, each about the size of a large walnut. After the kidney had been completely freed it was split along its convex border in its entire length. The two abscesses in question were the only pus foci present, but the parenchyma was very hyperemic and presented the macroscopical appearance of an acute parenchymatous nephritis. The renal pelvis was somewhat distended and contained about 30 ccm. of cloudy urine. On account of the evidences of a mild involvement of the left kidney, and given the two distinctly limited pus foci, it was decided to drain the kidney, as I felt that nephrectomy was not justifiable under the circumstances. The renal pelvis and kidney were drained by two good-sized rubber drainage tubes and the perirenal area was lightly packed with iodoform gauze. The renal incision was closed at the upper half of the kidney, the remaining lower half being left open to give exit to the drainage tubes. The fascia and skin were closed excepting for a couple of inches where the gauze and drainage tubes came out.

On the evening following operation the temperature made a decided drop and on the next day it had reached 100° F. The general condition was likewise greatly improved and a free discharge of urine and pus came away through the tubes. Forty-eight hours after the operation labor pains set in and the patient was delivered of a seven months' child after a labor of five hours. The child survived for a few hours only.

From this time on the general condition improved and the amount of urine voided by the bladder varied from 1,500 to 2,000 gm. in twenty-four hours. She began to sleep well and the drowsiness had entirely disappeared. On the sixth day one tube was removed and on the twelfth day following operation the gauze and the remaining tube were taken out. At this time the urine from the diseased kidney contained much less pus and some was collected which, on examination, showed that it contained a fair amount of urea, showing that it had not been functionally destroyed. The skin sutures were removed on the fourteenth day, the wound having closed perfectly.

Seven weeks after the operation there remains only a small fistula which is discharging so little that the dressings are changed only once a day. The urine now contains only a few granular casts, a trace of albumen and very few pus cells. The specific gravity is 1,012 and the amount of urea excreted in twenty-four hours is normal. I have no doubt that this patient will completely regain her health and that the fistula will have completely closed within a short time.

My three cases of pyelonephritis complicating pregnancy have all been pus cases and as yet I have not been fortunate enough to meet with the mild types, so many examples of which have been recorded in literature. From my limited personal experience it would seem to me that these cases are far from being as inoffensive as is generally supposed, but the reverse I believe is true, as far as the prognosis is concerned, in cases of this renal complication developing during the post-partum.

Attention is called to the inestimable value of Luys' separator in this case, because, on account of the advanced pregnancy, ureteral catheterism would have been difficult, if not impossible.

DR. A. L. CHUTE, Boston, reported a case of

SMALL FIBROUS OBSTRUCTING PROSTATE.

I wish to report a case belonging to a type that has interested me much of late.

The patient was a man sixty years old who had had bladder symptoms for about ten years; these symptoms began rather mildly, but two years ago they became pretty intense. His bladder was opened at that time and a large stone removed; a slight diaphragm-like bar at the bladder outlet was also found and divided. This man had relief for a time, but a year after operation he began to have his symptoms recur, and in order to be comfortable he was compelled to wear a catheter most of the time. He was practically unable to pass urine voluntarily. He had an infection, presumably with the micrococcus ureæ, that caused a splitting up of the urea and the precipitation of immense amounts of phosphatic material.

I was asked to cystoscope him as it was thought that

he might have a bladder growth. I found nothing, however, to suggest malignancy, but could see a little projection of the prostate into the bladder, as well as a slight raising of the bladder outlet above the level of the floor. With this patient lying on his back, I was unable to make out any prostate by rectum.

On the 25th of April I removed by the perineal route this man's prostate, getting but 2 dr. of prostatic tissue, and I think I got it out pretty thoroughly. After I had removed all the prostatic tissue I examined the bladder outlet, which was as tight and fibrous as could be. I cut the outlet down to the level of the bladder floor and also made a lateral incision on the left, leaving the bladder outlet as patulous as one commonly sees it after the removal of an hypertrophic prostate. This man passed his urine naturally in fifteen days. He left the hospital ten days ago. The point I want to bring out is that in some cases cutting the bar at the bladder outlet alone does not bring relief. The bar is produced by the prostatic changes and is not the whole obstacle. Likewise, taking out the prostate in a case of this type does not allow the bladder to empty itself. I have had one case recently when I took out all of the prostate and yet the patient could not pass urine. I had to cut the bladder outlet as well. In this last patient the obstructive prostate was also of the small fibrous variety.

Another point that was of interest to me in this case was that this patient had never had any urethral infection. I think many persons believe that the small fibrous prostate *always* follows a gonorrheal infection. I have found that in half of my cases of fibrous prostate that there has been no history of a gonorrhea or an acute prostatitis.

DISCUSSION. (Dr. A. L. Chute's case.)

Dr. Cumston. I would like to ask Dr. Chute if he expects necessarily to get a history of a former prostatitis or gonorrhea even when there has been one?

Dr. Chute. I must say that if a man tells me that he has never had a gonorrhea I am inclined to believe him. This depends somewhat on the general impression that I draw of the patient's intelligence and truthfulness. I see no reason why we should assume that every man who denies having had gonorrhea is either ignorant or untruthful. I see no reason why we should not accept the patient's story as regards this matter just as we accept it in regard to the occurrence of other diseases.

Question. I should like to ask Dr. Chute what he took away in the operation?

Dr. Chute. I first exposed the prostate by the usual transverse perineal dissections. I then made an incision through the substance of the prostate into the prostatic urethra. Then after introducing a tractor and pulling the prostate down I removed the presenting surface of the gland and also dug out with scissors and rongeurs all the deeper prostatic tissue that I could get, having the capsule practically an empty shell. I then split the fibrous ring at the bladder outlet, but removed no tissues. I open the urethra through the substance of the prostate because I believe in cases of this sort you are going to destroy the function of the internal sphincter, which I look upon as a sort of secondary line of defense in the way of preventing incontinence; one that is capable of developing a fair degree of control of the bladder, when the function of the cut-off muscle in the membranous urethra, the real sphincter, has been destroyed or injured. It is, therefore, especially important in these cases, when you are going to destroy the internal sphincter, to leave the membranous urethra absolutely alone in order that one may run no risk of injury to the cut-off muscle and its resulting incontinence.

Question. I would like to ask if this is the type of case that Dr. Chetwood recommends his operation for?

Answer. Yes, the same type that Dr. Chetwood has described and for which he advises the use of his incisor.

Dr. Hugh Cabot. I believe it is safer to cut through the bladder outlet with a cautery than with a knife. Dr. Keyes told me he had lost one of these cases from hemorrhage and now always uses a cautery. It seems to me that Dr. Chetwood's instrument is excellent for this purpose.

Dr. Chute. In only one of my cases has the cutting of the bladder outlet been attended with any real bleeding. In this instance it was simply annoying. When the operation is carried out as I suggest the field is very accessible and I believe any hemorrhage that might arise could be controlled with ease.

Dr. Watson. It happened in my early experience in prostatic work that I invented a cautery but I did not know this particular class of cases at that time. They are most interesting and important and hard to handle. Dr. Abner Post had a case that he reported that I think was one of them. He found almost no prostate. He started in to do a prostatectomy, being beguiled by bad example. He used a median incision and found the vesical orifice so hard that he could not force his finger through it. He took a Bigelow dilator and split it and the fellow got well. Mercier reported similar cases. He chiselled out the middle bar with his punch and also cut through with a cold instrument just as Gouley did later. All these things were things I studied when doing my early prostatic work. I want to ask, Are not a lot of these the cases that are sometimes spoken of as cases of "retention without mechanical obstacle"? I have a case that I believe is of this sort that I am going to operate upon shortly. His prostate is a small, nasty thing; judging from rectal examination, there is little or nothing to remove, but I may find that there is some projection into the bladder when I cystoscope him.

The internal sphincter, at the vesical orifice, does not amount to anything, as far as control of the bladder goes. You do a prostatectomy and you smash everything and yet the patient has control. The internal sphincter controls not a drop of urine, there is no question about it.

DR. R. F. O'NEIL, of Boston, reported a case of

CONTRACTION OF THE BLADDER NECK FOLLOWING AN ACUTE INFLAMMATORY CONDITION, CAUSING BEGINNING URINARY OBSTRUCTION IN A YOUNG MAN.

The patient was a man of twenty-six. First seen in consultation on Oct. 26, 1909, in regard to a swelling in the right side of the perineum corresponding to the position of Cowper's gland. There was moderate tenderness and deep fluctuation. There was a slight urethral discharge. The next day under ether a deep abscess was opened, the cavity admitting the finger tip. Gauze drainage and later on treatment of the urethra by sounds and irrigations was advised. Next seen Jan. 14, 1910, about two and one-half months later, for the reason that the sinus had remained open and had leaked on micturition since a few days after opening the abscess. He has been having sounds and irrigations. For the last month and a half he has been having chills which came on two days after instrumentation, lasted a short time and was all right again in twelve hours. He gets up once at night. There is no day frequency.

There is some difficulty of micturition. This has been more marked following instrumentation.

Examination. — External genitals negative, except for small fistulous opening at site of operation wound. Rectal examination: Prostate small, hard and non-tender. Slight urethral discharge, showing pus, epithelial cells and a few intracellular diplococci. Urine turbid, pale, alkaline, 1,020, albumen trace, urea 1.77, sediment, pus, epithelial cells and bacteria. Examination for tubercle bacilli negative.

Soft catheter passed easily to bladder, — size 16 French, — residual half an ounce. I was unable to pass a sound into the bladder. It felt as if the point were lifting the deep urethra. After considerable difficulty a cystoscope was passed by depressing the ocular end and using a good deal of pressure as the vesical neck was very tight. There was no cystitis. The ureter mouths appeared normal. There was marked beginning trabeculation of the bladder wall, the muscle bundles standing out very distinctly. The examination was short as it caused pain and the patient was quite nervous. He emptied his bladder of the examining fluid with greater ease and a better stream than he had had for months. Five days after the cystoscopy there was some soreness, but the stream was better and the urine clearer than for a long time. Heretofore the urinary difficulty had been increased after instrumentation. There was no chill and very little leaking through the fistula.

On going into his history it was found that about eight months before I had seen him first he had a severe attack of prostatitis with retention of urine requiring bed treatment and catheterization. There was a history of urethral disease for some time previous to this. This attack was followed by a second attack of prostatitis when he was quite sick, and from the history I judge he had had a prostatic abscess which ruptured into the urethra.

I regard this case as one of small contracted prostate following an acute inflammation and causing symptoms of beginning urinary obstruction in a young man as shown by the bladder changes, etc.

I do not know how common this condition is, but believe it is not generally recognized.

I believe in this case there is some pyelitis from the appearance of the urine and the fact that chills had followed unsuccessful attempts to pass sounds, the tissues being injured, causing edema, a consequent increased difficulty of micturition, with some retention of the infected urine.

I think the prognosis is unfavorable without some form of operative treatment. The difficulty of instrumentation is probably due to a change in the direction of the urethra as well as to a contracted bladder neck.

DR. BENJAMIN TENNEY, Boston, reported a case of

CHRONIC PROSTATITIS WITH OPERATION.

My patient was a man of twenty-four who had his first urethral infection in 1905. From that time on he had constant discharge. He reached me after the usual travels of these urethral cases, in 1907. He had pus at the meatus, pus in all urines, discomfort in perineum and rectum, two or three night urinations and a history of attacks of acute pain followed by chill and high temperature which were considered to be malarial. He had an attack of right epididymitis about three months after his infection. He was also impotent.

Examination showed no characteristic Gram-decolorizing diplococci in smears from the urethra, no special enlargement of the para-urethral glands, a prostate moderately large and tender, neither enlargement nor tenderness of either vesicle, good urethral delivery, bladder capacity of 4 oz. and some prostatic obstruction to the catheter, requiring a Coudé. He had a severe chill two days after my examination and again in seven days, evidently not directly due to my examination, and his temperature is said to have run up to 105° with enlarged spleen. Examination of his blood failed to show any plasmodia, but he certainly was a sick-looking young man. After three weeks' observation and my advice to have a perineal section for thorough drainage of his prostate, he disappeared for five months to consult various authorities and take a trip to Europe. During this time his pus was twice tested for tubercle with negative results, he was kept in bed for a time, cystoscoped, and washed and irrigated variously and plentifully. In the fall he returned, consenting to the operation, which was done at the Boothby Hospital Oct. 15.

Perineal section found a rather rotten prostate which was freely drained for nine days and less freely for some weeks after. To say that he has gained 30 lb., has married and has a healthy wife, and that he has had no further chill since the perineal section is both true and satisfactory. This final result passes over the tear into the rectum when clearing the prostate and the resulting Y-shaped fistula which connected the urethra with the rectum and with the perineum and made him uncertain whether gas, feces and urine would escape by their usual exits or by one of the other two.

A second operation under ether and a third with cocaine restored the integrity of the urethra and of the rectum and allowed the external fistula to close. At the second operation the prostate was found to be shrunken into a small fibrous mass which will probably cause retention before long. His urine is not absolutely clear even yet and he has had an epididymitis on the left side within the past month, but there is no visible urethral discharge, his wife is well and he considers himself so.

I have no doubt that there are many men walking about with urethral discharges due to infected prostates of the type of this one which I take to be the same as the type studied by Dr. Alexander. The important point to be reached is, When shall we stop our palliative and expectant or what I call "hopeful" treatment and really get at the infected area with efficient drainage?

I am coming to believe that a urethra running more than six months calls for something more than having its face washed. Continual pus from any other locality is considered a good and sufficient reason for real treatment and I think the probable sterility and urinary obstruction are sufficiently real, even if remote dangers, and call for definite surgical drainage of these infected prostates. Perhaps our neglect of real treatment is one reason why these patients deserve the reputation of being drifters, and perhaps the fault is more ours than theirs.

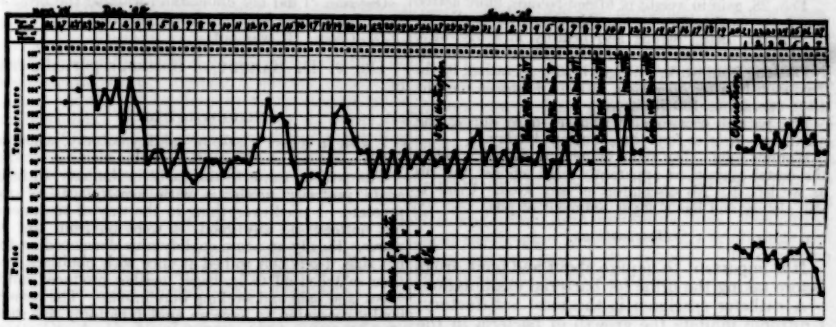
DR. H. M. CHASE, Boston, reported a case of

PYONEPHROSIS; CONGENITAL CYST — SINGLE KIDNEY.

Boy, age fourteen years, whom I saw in December, 1908. In 1903 he had two attacks of chills and fever with pain on urination; one similar attack in 1907.

Otherwise in apparently good health until Nov. 12, 1908, when he had two weeks of not feeling well and on Nov. 26, 1908, had chills followed by fever to 105°, severe headache and vomiting.

Urine high colored, very thick, with muddy sediment, sharp pain in the right side after running, considerable pain on urination. Urinates twice at night.



Nov. 27 and 28, continued fever, a great deal of pain in the right side most of the time and sore to the touch. The temperature was recorded by the mother, as seen on the accompanying chart, from Nov. 26, 1908, until Jan. 12, 1909. On Dec. 24, 1908, the history of pus in the urine, temperature, chills and tumor in the region of the right kidney was given me by the family physician, who sent me a catheter specimen of urine.

There was a history of night sweats. No vomiting during the last four weeks. The urine, averaging 4½ pints in twenty-four hours, was voided twice at night and five or six times during the day.

The urine was turbid, odor not foul, light straw, 1,015, acid, albumen present in large quantity. Sugar absent. Large quantity of pus. Urea .88% = 18 gm. Total solids, 68 gm. No tubercle bacilli nor gonococci found, few small caudate and few epithelial cells. No blood seen. Hemoglobin, 95%.

Family unwilling to consider operation. Request to stop urotropin for five days until Jan. 1, 1909, to get urine free from antiseptics.

Jan. 1, specimen of urine sent by mail, no preservative, taken to Dr. Leary's laboratory, growth of colon

Pyonephrosis of single kidney.

The patient's family was strongly opposed to the consideration of any operation.

The specimen was taken to Dr. Leary's laboratory. Dr. Strong reported a turbid fluid with heavy sediment. Growths were started on culture media and a centrifuged specimen was injected into guinea pigs, which resulted in the report of absence of tubercle bacilli. By the microscope nothing could be identified but pus. The growth on milk agar showed staphylococcus albus, one frequently found in urine but not usually or necessarily associated with pus production. It was said to differ from the skin albus of the same name. No streptococci nor colon bacilli found. A vaccine of this culture was used for a few days when inquiry showed that the patient had been given urotropin, gr. x, three times a day. Vaccine and urotropin were stopped.

I saw the patient for the first time on Dec. 27, 1908. A dark-complexioned boy, age fourteen, reticent, fairly well-nourished; appetite fair, tongue slightly coated, bowels regular daily. Heart and lung examination negative. Abdomen soft, no distention nor tenderness. No spleen felt, liver above costal margin.

Left kidney can be felt on deep inspiration (this observation was inaccurate as there was no left kidney). A mass on the right side in the region of the kidney moved with respiration; it was not tender to pressure, the size of my fist, quite freely movable up and down but not laterally, mainly above the crest of the ileum. The mass is in the region where pain has existed.

The tumor was high for appendix, there was no history of pain along the ureter nor into the bladder or penis. The penis, very large for boy of his age, suggested masturbation. Testicles and scrotum negative, rectal examination negative, examination of the spine negative.

bacilli. Dr. Leary said the first culture was inhibited by the urotropin which does not kill the bacteria.

The growth of staphylococci undoubtedly due to contamination, though it is very rarely a cause of bacteriuria and cystitis. Vaccine made of colon bacilli, ½ ccm. = 50 million.

Dose, minims iv, every two days, increasing up to minims viii.

Jan. 12, 1909, reported by letter, normal morning temperature, high fever at night. Patient has seemed to gain in weight and in general conditions. Mass in right side increased.

Urine examination showed approximately the same amount of pus, several washed-out blood cells and a few questionable crystals.

Jan. 13, 1909. Patient has been up about the house every day. Looks better. Chills the last three days. Left kidney palpated (again mistaken).

Mass in right side as before.

Mother says urine clears considerably at times, then when chills, fever and pain come on the urine is much more turbid, with increased sediment. Operation again advised and considered by family.

Jan. 20, 1909. Operation, Dr. Tenney assisting. Transperitoneal nephrectomy contemplated. Incision through right rectus; examination of left side by Dr. Tenney and myself revealed no kidney on that side. Nephrectomy not possible. Incision was closed by layers with catgut.

Right loin incision from twelfth rib toward groin; mass exposed; lower half of kidney a large cyst (dilated pelvis and thin renal wall). Kidney tissue about seven inches long. Sac opened and thin gray fluid evacuated. No stone found; nothing to suggest tuberculosis. Upper half of kidney feels like solid renal tissue.

The sac wall was removed close to the solid renal tissue, the edges were inverted and sutured with catgut.

Was unable to locate the ureter opening.

Upper pole of the kidney very high under the diaphragm. The lower pole was rotated outward and upward and sutured to the twelfth rib, which straightened the ureter. Two gauze drains inserted into the wound, muscle and skin sutures of catgut.

The chart shows the post-operative temperature.

Feb. 4, 1909, colon vaccine given every two days for two weeks.

On Feb. 7 the urine had cleared greatly but still contained pus. Abdominal wall solid, loin wound solid except for wicks which were gradually removed.

Feb. 21, less pus than before the operation.

Feb. 28, gain in weight of fifteen pounds, more active and better health than for months. Urine much clearer.

May 22, 1910. Strong and healthy in every way, good appetite. Can run and play without discomfort. No fatigue from work. Weight before operation, 90 lb. Two months after operation, 105 lb. Eighteen months after operation, 130 lb.

The patient occasionally urinates once during the night, and three or four times during the day.

Wounds solid. The right kidney not palpable below the costal margin, is apparently high against the rib as we left it. No discomfort of any kind. Urine is still cloudy and has a slight sediment of pus.

Observations.

It is important to inquire about and omit drugs before taking the urine for bacterial examination.

A catheter specimen is the most satisfactory. Urotropin inhibits the growth of bacteria in the urine, but does not kill them.

When confident, after careful palpation of the abdomen, of the existence of two kidneys, it is important to verify it by some more definite method before doing any radical operation on either kidney: either by ureteral catherization when practicable, which, by the way, cannot be relied upon as cases of two ureters from a single kidney have been reported, or by exploratory laparotomy.

No vaccine in the presence of mechanical obstruction can be expected to be efficient. If conditions permit, be sure of an anchored kidney with a straight draining ureter.

DISCUSSION. (Dr. H. M. Chase's Case.)

Dr. Cumston. This case is rare and remarkable from the pathologist's standpoint. Cases of pyonephrosis would occur where a congenital cyst of the kidney became infected. These cases are occasionally met with, and those that have been reported are autopsy findings. The condition has been found on one side only, I believe, in the large majority of cases. The kidney has been entirely consumed by the process and has been represented by a single sac.

There is another point which I was glad to hear brought out, because opinions differ largely on the question. That is the mobility of the kidney on respiration, some writers stating that it cannot occur. I have been hesitant in putting forward my belief in public, but I am positive that in many cases where the kidney is enlarged, where the organ is not adherent, that the renal gland can be felt easily to follow the movements of respiration. Therefore, when a tumor on one or the other side of the abdomen moves with respiration, it should not be concluded that it is not renal in origin.

Dr. H. Cabot. Ureter catheterization does not necessarily show the presence of two kidneys. Within a year I have had ureters catheterized and urine drawn from two ureters, but only one kidney was present at operation.

Dr. Watson. In regard to the normal mobility of the kidney. I am surprised, for I thought the fact was generally accepted. I have measured a great many of these kidneys. The amount of movement of the ordinary kidney in respiration is one-half to one and a half inches, in the living.

In regard to the accuracy of ureter catheterization, there are several instances on record of multiple ureters from one or both kidneys which have led to serious errors in diagnosis.

Question. I did not understand whether the urine in Dr. Chase's case was free from bacteria.

Dr. Chase. It was not.

DR. J. D. BARNEY, of Boston, reported a case of

EPIDIDYMOTOMY.

I wish to report a case of epididymotomy, which as yet is not a common operation in this vicinity.

The patient came to me early in January with an acute posterior urethritis with involvement of the prostate. I tried everything in the way of treatment, but nothing did any good. It went on from bad to worse. Finally an acute epididymitis developed on the left side. I put him to bed at once with poultices, and then switched off to ice-bags; neither produced much effect, and pain and swelling were intense. The patient finally consented to have an epididymotomy five days after the onset of the disease.

The day after operation the temperature was normal; it had been up to 101. The pain was absolutely relieved and the epididymis was only slightly tender. The urethral discharge stopped almost at once. This was not wholly due to the operation, however, for, as you know, it often subsides at once after the onset of an epididymitis.

Twenty-four hours later the right epididymis became involved and after a wait of thirty-six hours this was also opened in the same way. Again the temperature, which had flared up, went down to normal and remained so. In the same way all pain and tenderness left the epididymis.

Owing to the tremendous edema of the scrotum its layers were very difficult to distinguish. In the first operation I did not recognize the tunica vaginalis for some time. On opening the tunica it was found much engorged and contained about 3 dr. of serous fluid. A "chicken-fat" clot, about as large as my thumb, was adherent to the epididymis and testicle, and dense adhesions had formed between the latter structures. The clot was scooped away, leaving a red, bleeding surface on the epididymis. The globus major particularly was involved on each side. Multiple punctures were made with the knife throughout the epididymis. Nothing was found except in the body of the left epididymis, where there were several minute abscesses which exuded a drop of creamy pus containing gonococci. Elsewhere the punctures elicited only free hemorrhage from the congested organ. On the right side no pus could be found, but the fluid in the tunica, the clotted lymph and enormous congestion were the same as on the left.

The operation made a startling difference in this case. About ten days after operation the two epididymes were essentially normal subjectively and objectively. It would require imagination to say that

there was anything unusual beyond a moderate thickening and induration. The urethral discharge has never reappeared, the frequency has subsided and the prostate is no longer tender and congested.

Now as to the question of sterility, which intervenes in nearly 50% of these cases. I have examined the prostatic secretion several times since operation, but no spermatozoa are to be found. They may appear later. It is quite possible that there is still enough edema and induration of the epididymal tubules to prevent the passage of spermatozoa. Several tests by culture and microscopic examination show no gonococci.

I mention this case because it is a rather rare operation as yet, and although I lay a great deal of stress on the value of ambulatory treatment by means of compression with rubber dam, I think this operation is of the utmost value in cases of exceedingly painful and acute epididymitis. Indeed, I am not at all sure that it should not be done in every case of acute epididymitis. It has a tendency to cut short the course of the urethritis and prostatitis by affording efficient drainage of the seminal ducts. It is claimed to lessen the chances of sterility, but this has not been the case in my patient as yet.

DISCUSSION. (Dr. Barney's Case.)

Dr. Benj. Tenney, Boston. Relief of pain from incision into the swollen tissues of the epididymis is both prompt and permanent. The last patient on whom I have tried it was seen with Dr. A. D. MacLennan. For some time we were uncertain whether we were dealing with a severe right-sided epididymitis and a vesicular abscess or whether there was an appendicitis mixed up with the venereal condition. As always, there was great tenderness over the right vesicle on rectal examination, which may also be found when the inflamed appendix lies in the vesico-rectal fossa. As often happens, there was tenderness above the inguinal canal up to the anterior superior spine. The absence of any smooth swelling about the vesicle and the slight rigidity of the right abdominal muscles led us in the right direction. Removal of the appendix with incision into the epididymis quickly stopped the pain and vomiting. The scrotal incision was still granulating when he left the hospital at the end of ten days. The tenderness was all gone and the induration was less than I have ever seen it in so short a time. I am sure incision is the treatment for all patients who will permit it.

Dr. Hugh Cabot read a paper on

A CASE OF MYXO-FIBRO-SARCOMA ORIGINATING IN THE GREAT OMENTUM WITH INVOLVEMENT OF THE BLADDER AND SMALL INTESTINE.*

In Memory of Dr. Baumgarten. — The Alumni Association of the Medical Department of Washington University has appointed a committee to raise funds for the erection of a memorial tablet of the late Dr. Gustav Baumgarten, to be placed in the Medical Library Building beside those in memory of Drs. Gregory and Boisliniere. — *Jour. Am. Med. Asso.*

Medical Progress.

RECENT PROGRESS IN GENITO-URINARY SURGERY.

BY FRANCIS S. WATSON, M.D., AND PAUL THORNDIKE, M.D.

EXPERIMENTAL RESEARCH.

Barney [1] has investigated the effect of intraperitoneal division of one ureter experimentally from the pathological and the bacteriological standpoints from operations on 40 animals and clinically from 6 cases in the literature and 29 cases collected in answers to personal letters to surgeons. It appears that "the abdomen may bear without damage and even, in some cases, without severe reaction, the effusion of a certain amount of sterile urine"; that efficient adhesions may be promptly formed; that the divided ureter may become quickly occluded by adhesions or blood clot; that general peritonitis probably occurs in those cases where such occlusion does not take place or where the urine is septic. Dogs and cats always recovered and showed nearly always at autopsy adhesions between omentum or gut and the wound, and in one half the cases free abdominal fluid containing urea. The peritoneal cavity gave positive cultures in all dogs and cats and one half of the rabbits. The organism was practically always a coccus.

TUBERCULOSIS.

From an extensive experimental investigation of the routes of extension of urogenital tuberculosis in rabbits, Sawamura [2] reaches the following conclusions:

(*a*) Extension of vesical and genital tuberculosis to the kidney seldom occurs.

(*b*) Direct ascending infection of the kidneys with tuberculosis from bladder, without obstruction of the urinary stream, is possible only when a relatively high pressure prevails in the contractile bladder and an antiperistaltic movement of the ureter sets in.

(*c*) Ascending renal tuberculosis may be produced by tuberculous involvement of the lower part of the ureter, with consequent stricture, stagnation and dilatation.

(*d*) Lymphogenic ascending renal tuberculosis theoretically cannot be denied, but was not surely determined.

(*e*) Tuberculosis of the testicle and epididymis as a rule extends urethrally.

(*f*) It may also extend by the lymphatics, though more rarely.

(*g*) Tuberculosis of the epididymis often extends downward to the testicle.

(*h*) Tuberculosis of the testicle and epididymis often remains for a long time local, without spreading to the rest of the genital apparatus.

(*i*) In primary tuberculosis of the testicle, the spermatic cord is often also affected.

(*j*) The lymphatics of the testicle mostly lead to the lymph nodes along the inferior vena cava at the level of the termination of the internal spermatic vein, and those of the epididymis to the nodes along the hypogastric vessels.

(*k*) The proximal part of the vas may be infected by tubercle bacilli from the urine.

(*l*) Tuberculosis of the epididymis may arise from descending tuberculosis of the urinary passages when the orifice or lumen of the vas is plugged with granulation tissue, and tubercle bacilli are transported to the testicle from stagnation of the secretion and exudate.

(*m*) Ascending tuberculosis of the epididymis without involvement of the vas is rare, though possible.

KIDNEY TRANSPLANTATION.

Carrel [3] reports at length the technic of his autoplastic transplantation of the kidney and the experimental investigations which led up to its successful performance, and summarizes as follows the facts attained by this important piece of research:

(1) A dog's kidney, which has been extirpated, washed and reimplanted, is capable of functionating in an entirely normal fashion and for a long time after operation. In case of simultaneous removal of the other kidney it may successfully carry on the entire renal excretory function.

(2) The technical procedure of kidney transplantation is at present sufficiently good to avoid every immediate or later complication proceeding from the blood vessels.

(3) The tolerance of the operative interference of the temporary interruption of the circulation, of the perfusion and of the severing of nerves is shown by the excellent function of the organ more than eight months after operation.

SCLEROTIC PARANEPHRITIS.

In this form of renal inflammation the kidney becomes embedded in a mass of fibrous tissue. Operation is indicated because, by the time the process has reached this stage, the organ has practically ceased to functionate and its removal is indicated. Zuckerkandl [4] shells out the organ, making no effort to remove its capsule with it. He calls the procedure intracapsular nephrectomy.

VACCINES.

Hartwell and Streeter [5] and Hartwell,[6] conclude that bacterial vaccines

(1) Are efficient in relieving symptoms in mild forms of cystitis, but have a less marked effect on pyuria.

(2) Are without value in severe forms of cystitis.

(3) Probably hasten the recovery of pyelitis.

(4) Have no influence on bacteriuria.

Hartwell thinks that vaccines "will probably furnish us a means of attacking post-operative foci, such as an infected ureter stump, which are difficult otherwise to clear up.

Eyre and Stewart [7] found that in acute gonorrhea the gonococcus vaccine is markedly toxic and exerts a profound influence. A stock vaccine comprising a dozen different stains gives results only slightly inferior to an autogenous vaccine.

In a carefully carried out research with many cases, Schmidt [8] concludes among other things that serum therapy in gonorrheal cases seems to be used to the greatest advantage in acute or subacute gonorrheal toxemic cases — those cases which are too often referred to as "gonorrheal rheumatism"; that serum is of no practical value in the inveterate long-standing cases; the serum-therapy has not been of as great value in metastatic or gonococcemic conditions. The vaccine mode of therapy, he says, has shown satisfactory results in true gonorrheal arthritic conditions — when undoubted metastatic conditions are present and where a gonococcemia is probably present. In the very acute attacks especially good results were noted.

TUBERCULIN.

The belief that tuberculin has a real place in the therapy of surgical tuberculosis seems to be steadily gaining ground as a result of the work which is being done in the clinics of this country and of Europe.

Sanborn [9] summarizes the indications for its use as follows:

(1) In case of organs involved which cannot be extirpated, such as the bladder;

(2) In case of any organ in which tuberculosis is very early and in which disintegration has not taken place to any considerable extent;

(3) In case of tuberculosis of both kidneys where it is deemed unwise to operate either;

(4) Post-operatively in case that it is apparent that all tuberculous tissue was not removed or where organs that were involved could not well be extirpated;

(5) In any case where bladder involvement is present;

(6) In any case where there is a suspicion that tuberculous tissue has been left behind;

While Hugh Cabot,[10] in describing the practice at the Massachusetts General Hospital, discriminates between cases in which the disease has been apparently removed, as in unilateral kidney infections without bladder involvement, and those cases in which some disease remains although its principal focus has been removed.

In the former class tuberculin is used after the method advised by Tondeau, while in the latter the injections are continued at a maximum dose until the patient is free from symptoms or until six months have elapsed.

ETIOLOGIES.

In a discussion of the etiology and pathology of the *undescended testis* the writer [11] insists that the imperfections in an undescended testis are the cause of and not the result of its failure to reach the scrotum.

In a good paper on kidney and ureteral stone, Bevan [12] insists that *renal colic* is due to a greatly increased intrarenal tension and that the passage of a stone does not necessarily cause any pain. He cites a case in which the progress of a stone through the ureter was watched by successive x-rays and no pain was experienced.

The writer [13] throws aside the commonly mentioned causes for *varicocele* and stanchly

upholds the belief that there is a congenital diathesis which serves as the etiological factor.

Paul [14] considers that *prostatic hypertrophy* is not due to a chronic inflammation of septic or specific type, nor to a neoplasm, but that it is an involution change similar in character to that which occurs in the mammary gland. He presents his evidence at length in support of this theory.

CANCER OF PROSTATE.

A careful study of 111 cases by Young [15] and a comparison with cases of benign enlargement of the prostate have added much to our knowledge of this disease. He finds that it is a far commoner disease than was ever believed possible; that often a diagnosis can be made before the disease has passed the confines of the prostatic capsule; that there is no evidence to show that these cases are degenerative from benign hypertrophies.

FUNCTION OF KIDNEYS.

The writer [16] had the unusual opportunity of repeated and long-continued study of the urine secretion in a case of ectopia vesicæ when naturally it was not necessary or possible to use a cystoscope. He reached the following interesting conclusions. The "diuretic quotient," or average amount secreted per minute, varied usually between 1 and 2. Almost half an hour after taking a considerable amount of fluid there was rapid rise in the diuresis, which fell in another half hour to its former level; with beer it lasted two hours. These observations show how rapidly the body gets rid of surplus fluid. In case, however, little fluid had been taken the day before, the ingested liquid was stored up and no increase in diuresis took place. The secretion of urine was smaller and more irregular in the lying than in the upright and Fowler's position. Urine spurted from the ureter about once in ten seconds, and about .3 ccm. at a time.

CHEMISTRY OF URINE.

Cantelli [17] describes the chemical characteristics of a group of substances which he isolated from the urines of certain patients and says that the presence of these substances in the urine may often give evidence of a renal lesion at a time when albumin and other indications of a nephritis are entirely lacking.

NEW TECHNIC.

A new method for the removal of bladder growths must always command attention at a time when the present methods at our disposal are so unsatisfactory in their end results. Beer [18] describes a technic he is beginning to use which consists in using high-frequency currents through a Nitze double-catheter cystoscope. He calls his paper a brief preliminary report, but in it he has distinctly demonstrated the technical possibility of his method of work.

Renal Pelviotomy.

Mayo [19] shows how a flap of fatty fascia may be used in closing the wound in the renal pelvis in such a way as to give this procedure a wider field of usefulness.

Operations upon Upper End of Ureter.

Cabot [20] describes a new technic for reaching stones which lodge high up in the ureter just below the kidney pelvis and again at a point at the pelvic brim as follows:

The ureter in the first situation is, I believe, best reached by an oblique muscle-splitting incision, starting at about the tip of the twelfth rib and running downward and forward to a point about midway between the anterior superior spine of the ilium and the umbilicus. The fibers of the external oblique are separated in line of the incision, those of the internal oblique and transversalis practically at right angles to the incision. If the separation of the muscles is freely made, good access is obtained to the upper half of the ureter. After the muscles have been separated, the peritoneum is pushed back and the ureter readily found lying upon the psoas muscle, though its tendency to be turned up with the peritoneum should not be forgotten.

Stones situated at the brim of the pelvis may be conveniently reached by an incision in the same line as the one above described, but beginning where the other stopped at a point nearly midway between the anterior superior spine of the illum and umbilicus and continued downward to the junction of the inner and middle thirds of Poupart's ligament. Here again the peritoneum may be pushed back and the ureter readily found at the point where it crosses the bifurcation of the common iliac artery.

Operation on the Lower End of the Ureter.

Gibson [21] describes technic of an operation for the purpose of reaching the lower portion of the ureter by an extraperitoneal route. A curved incision is made extending at first horizontally outward from just above the symphysis pubis, bending upward along Poupart's ligament to a vertical direction opposite the anterior superior spine of the ileum. By retraction of muscles and incision of the transversalis fascia the peritoneum is exposed; the peritoneum is then pushed upward exposing the ureter, which can then be drawn up into the external wound. The ureter after incision can be closed by a double row of sutures and the wound closed without drainage. Two cases are reported.

Operation for Cancer of Bladder Fundus.

Hagner [22] describes an operation for these somewhat rare cases in which the removal of the growth is accomplished with no injury to the tumor mass.

The following is a description of the operation as employed in one case: The bladder was irrigated, and, on account of bleeding, adrenalin 1: 10,000 was instilled and allowed to remain five minutes. The bladder was then distended with 350 ccm. of salt solution, and a Nitze cystoscope was introduced. This was held in place by an assistant, while a suprapubic incision down to the bladder wall was made. The prevesical fat was well separated and the tissues well retracted by wide lateral retractors so as to give a good

exposure of the bladder wall. The growth was then inspected through the cystoscope, the right hand holding the cystoscope; with the left, a needle was pressed on the fundus of the bladder and the dimpling caused thereby was readily seen through the cystoscope. The needle was carried first to the left of the growth at a sufficient distance to give a margin of healthy bladder wall; it was then plunged into the bladder, being held in place by an assistant. The same procedure was carried out at the right of the growth and at the lower border. An attempt to place a needle above would have penetrated the parietal peritoneum, as this was involved in the growth. A sharp knife was then carried to the outer side of the three needles placed around the growth, the portion of the bladder wall to be removed being clamped at its cut edge as soon as the incision was started. The bladder wall containing the growth was lifted up by the clamp and held by an assistant. The fluid left in the bladder was removed by a large syringe through the suprapubic wound to prevent its entrance into the peritoneal cavity. The incision in the bladder wall was then carried upward into the peritoneal cavity and a portion of parietal peritoneum covering the growth was removed. The bladder and peritoneal wounds were then closed by two rows of sutures, a suprapubic drain being left in the bladder.

RADIOGRAPHY.

Renal Pelvis.

After considerable investigation the authors [23] found that a 50% solution of cargentos (a colloidal silver oxide) gave x-ray shadows of the greatest density and was absolutely non-irritating as a fluid for diagnostic injection of the renal pelvis. In order to avoid over-distention of the pelvis, and consequent colic, they have used gravity injection, allowing the solution to run into the ureteral catheter from a graduated burette elevated two feet until the flow ceases.

Stones in Lower End of Ureter.

Cabot [24] describes and illustrates with photographs the reasons why stones in this location may fail to show even with good technic. His suggestions if confirmed by further experience should prove of real value.

A Case of Filarial Hematochyluria.

The authors,[25] after quoting one or two similar cases, report a case of their own which was apparently cured by quinine and the x-ray.

NEW INSTRUMENTS AND APPARATUS.

An Improved Method of Measuring the Capacity of the Renal Pelvis.

Baker [26] describes an instrument for the above purpose by means of which one can get an accurate idea of the capacity of the kidney pelvis under known conditions of pressure, thus obviating the tendency to produce renal colic as a result of uneven and unknown amounts of pressure which must necessarily result from the use of a syringe to force the fluid through a catheter.

A Device for the Prevention of Bleeding in Bladder Operatons.

The writers [27] describe their method of operating on prostatic and bladder cases after binding all four limbs of the patient with gauze roller bandages so completely and tightly that the operations are done with all four extremities blue. In this simple way the writers claim practically bloodless operations with no bad after-effects, and they earnestly recommend the procedure to the profession.

A Cysto-Urethroscope.

Stimulated by the success of the Goldschmidt instrument in examinations of the deep urethra, the writer [28] describes another and, to his idea, a better instrument which employs the Nitze type of indirect or right-angled telescope. He claims his instrument does away with the partial field, distorted image and the traumatism caused by the large window of the older instrument.

A New Catheter Container.

Barney [29] describes an ingenious, cheap and apparently efficient container for ureteral catheters, consisting chiefly of a piece of rubber tubing one or two inches longer than the instruments it is to contain.

RARE AND INTERESTING CASES.

Ureterocele.

The writer [30] details two cases of this very rare occurrence and reviews twenty-two others. He says the conditions should be suspected when a cord is found in a hernial sac at operation.

Family Hematuria.

Aitken [31] reports a family of seventeen persons, ten of whom have suffered from hematuria. In spite of an apparently prevalent opinion to the contrary, he insists that a very guarded prognosis should be given in such cases.

TOTAL EXTIRPATION OF THE BLADDER COMBINED WITH HYSTERECTOMY AND IMPLANTATION OF THE URETERS IN THE LOIN.

Martin [32] reports having performed the above operation upon a negress of forty-three years of age, in a case of cancer of the lower part of the uterus involving the floor of the bladder and the orifice of the right ureter. The operation was performed as follows:

Tamponade of the vagina, Trendelenburg position, medium laparotomy. Ligature of the cervix, of the round ligament and of the uterine vessels. Ureters exposed and divided 8 cm. from the bladder; divided ends of the ureters carried to the lumbar surface and drawn out a short distance through the incision made in either loin to allow of their being passed through the skin. A small catheter was passed into each of the ureters thus placed and secured there. The uterus, bladder and neighboring portion of the vagina were then removed and the peritoneal cavity shut off by a lock stitch.

Two days later the catheters were removed because of the insufficient drainage afforded by them, the ends of the ureters were split longitudinally and attached to the skin. The patient was able to keep the loins clean and could resume an active occupation. The ultimate result is not mentioned.

REPORT OF A CASE OF PRIMARY TUBERCULOSIS OF THE BLADDER.[33]

The patient was a man of sixty-two years of age. Thirty years before entering the hospital he had a traumatic rupture of the urethra, extravasation of urine and perineal fistulæ which persisted up to the present time. In 1908, external perineal urethrotomy was performed. Convalescence was uneventful up to the fourth week; at this time a sudden rise of temperature and severe dyspnea occurred and the patient very shortly afterward died.

The *autopsy* revealed the following conditions: Fatty degeneration of the heart. Emphysema of the lungs. On the apex of the left lung a small focus of cicatricial hardening which was entirely encapsulated. The spleen and the capsule of the liver and the diaphragm presented large and thick cartilaginous plaques. Carcinoma of the stomach at the pylorus. The *bladder* contained a purulent, cloudy liquid. Muscular columns were very marked upon the surface. Scattered over the entire inner surface were numbers of small projections of a grayish and slightly translucent appearance of the size of a millet seed and surrounded by circles of hyperemia. The center of these projecting masses was whitish and opaque. The epithelium was destroyed at these points. On a level with the entrance of the urethra a number of these individual projections had run together forming an irregular ulcer of about 1 cm. in diameter which was also surrounded by a circle of hyperemia. The prostate was hypertrophied and the size of a small apple.

Microscopic examination of the small bodies described above showed small rounded masses of leucocytes infiltrating the submucosa and surrounding numerous and very characteristic giant cells. These cells were very large and their nuclei were arranged "*en calotte.*" The nodules presented clearly the typical appearance of tubercle. They did not find necrosis in any of the different microscopic sections of the nodules, which fact would seem to indicate that they were of recent origin. The only other tuberculous process that could be found anywhere in the body was the small focus of fibrous tissue of long standing in the apex of the left lung, which showed no softening and which was thoroughly encapsulated. There was no sign of a tuberculous process, recent or ancient, in any organ of the genito-urinary tract or in any other part of the body, and no sign of miliary tubercle elsewhere to offer an explanation that the lesions of the bladder could have originated by hematogenous infection from some other focus of the disease; on the contrary, the disposition of the vesical tubercles, which were more numerous and which had united in one place into a superficial ulcer near the internal orifice of the urethra and, becoming fewer on the sides of the organ and finally being absent at its summit, indicates that the bacillus entered the bladder and infected it from the urethra. Mouchet thinks it probable that the bacillus gained entrance to the bladder from the fistulous tracts in the deep urethra which connected it with the surface of the perineum.

THE PATHOLOGY AND THERAPY OF ANURIA.

In 1903, Kreps[34] published several cases of calculous anuria in which he relieved the condition by ureteral catheterization of both kidneys. The urine drawn from the unobstructed kidney in these cases immediately after the overcoming of the anuria was perfectly normal, which fact Kreps regarded as a proof of the existence of a reflex anuria affecting the unobstructed organ and having its source from an inhibitory influence originating and transmitted from the obstructed kidney. In the publication referred to above Kreps reports some other cases of anuria which still further go to prove the existence of a reflex anuria. In the first of these the same experience with regard to the demonstration of the normal condition of the unobstructed kidney being subjected to a reflex anuria was repeated. A further point of interest was added in this instance by demonstrating the condition on two different occasions with an interval of three years in the same patient, the left or unobstructed organ on both occasions having its function suppressed by reflex inhibition proceeding from the right kidney which was obstructed by a calculus in the ureter.

In the second case the obstruction of one side was produced probably by the blocking of one ureter with blood clot. Here, too, the second or unobstructed kidney was shown to be normal by urinary tests.

In three instances of obstructive anuria, both of the kidneys were more or less pathological. They illustrate the relief of the anuria by means of the use of ureteral catheters and injections through them of glycerine, but are not demonstrations of reflex anuria of an unobstructed and normal kidney.

PHYSIOLOGICAL FUNCTION OF THE PROSTATE.

The statements made by the authors[35] with regard to the physiological functions of the organ relate to three separate questions, the first being the office of the muscular part of the gland, the second its external secretion and the third its internal secretion.

With respect to the first, they conclude that, although a muscular organ, it has but little to do with the closure of the bladder, but that its muscular constituents are concerned in the expulsion of the secretion of the glandular portion of it. This explusion of the secretion takes place at the termination of coitus and is produced through stimulation of the branches of the sacral plexus transmitted to the hypogastric plexus and which reaches the prostate through these intermediate branches.

Lamare is quoted as holding the view that the prostate does not perform any glandular function until puberty; that the glandular activity reaches its culminating point between the ages of twenty-six and thirty, and that somewhere between forty-five and fifty years of age the fibromuscular elements increase at the expense of the glandular ones.

With reference to the relation of the prostate to the genital function, the following facts are recalled: That the development of the prostate in young animals remains arrested at whatever point it may have reached when castration is performed upon them; again, that the glandular portion of the organ atrophies and disappears when the testicles are removed. Casper found that the center of the prostate where it surrounds the urethra in a dog which had not reached puberty had no glandular structure. According to Walker, the injection of testicular extract in male dogs which had been castrated, delayed or prevented atrophy of the prostate, while the atrophy proceeded progressively when no injection was given: the development of the prostatic glands proceeds almost absolutely in correspondence with that of the testicles.

A CASE OF RENAL CALCULUS PRODUCING NO SYMPTOMS FOR FIFTY YEARS.[30]

Patient, a man of sixty years, had had typical attacks of renal colic on the right side as a child. These had then ceased and there had been no evidence pointing to renal calculus for the next fifty years. At the end of that time there was a return of the colic on the same side accompanied by hematuria. The patient was operated upon. The right kidney found to be wholly destroyed by a stone almost as large as the fist, which was composed largely of phosphatic salts. The kidney was removed and the patient made a good recovery.

Read by title. No discussion.

XI. CASE REPORTS ILLUSTRATING OCULAR AFFECTIONS DUE TO INTRANASAL AND ACCESSORY SINUS DISEASE.

DR. LEWIS A. COFFIN, New York.

DR. FRANK J. PARKER, New York, said that he had had the privilege of working with Dr. Coffin and had taken all these fields with the self-recording perimeter under the best conditions of daylight. The disks used were 10 mm. square. The fields were taken several times, and some were taken by the house surgeon also; few if any errors were found, and these were very slight. A line of work of this sort will be a great help to the ophthalmologist; some cases go from one to another, and no one can fit them with glasses. Two of these were just such cases. They were normal with the ophthalmoscope. There is a class of cases with optic atrophy, and it has been almost a rule that if no reason can be found for the condition, the patient is put upon iodides. It is probable that many of these cases that have been injured by iodide of potassium have been due to sinus disease, especially of the ethmoid and sphenoid.

Some of these cases of Dr. Coffin did not have sinus trouble, but had intranasal swelling of the turbinates, etc., with a normal optic nerve. These cases should be divided into two classes, one due to circulatory disturbances, and the other to peri-neuritis causing swelling, and this, beginning optic atrophy. These cases show first in the peripheral fields where there is less visual acuity. He expressed the hope that others would work along this line. Dr. Coffin and he were anxious to find its value in diagnosis. Up to the present time it would seem to be of great value.

DR. CORNELIUS G. COAKLEY, New York, said that two months since he had had three patients with sinus involvement whose eyes were examined by Dr. Wheeler, and in none was there any contraction of the visual field. In another case of marked unilateral involvement both Dr. Wheeler and Dr. Parker examined the patient's eyes and they were found to be practically normal; so that while the condition presented by Dr. Coffin undoubtedly occurs in some cases, we are just at the beginning of the subject. It is a very valuable symptom, and is evidently caused by some form of interference with the vision.

DR. H. L. SWAIN, New Haven, expressed deep appreciation of the manner in which Dr. Coffin had presented the subject, and of the help afforded by Dr. Parker's admirable illustrations. He himself had recently been studying what Onodi says in relation to the optic nerve to the walls of the sphenoid and the posterior ethmoid sinuses, and feels that we are almost open to censure that we have not appreciated this

before. It is not any wonder that the optic nerve is involved; the wonder is that it ever escapes with this serious pressure inside of this cavity.

Dr. Greenfield Sluder, St. Louis, cited the history of a patient illustrating the involvement of the optic nerve as expressed by Dr. Swain.

Dr. Coffin, closing the discussion, emphasized Dr. Coakley's remark that we are only at the beginning of this line of investigation. So far, he himself has not found a case positively diagnosed as having disease in the ethmoid or sphenoid that has not shown contraction in relation to the apparent involvement. The case reported by Dr. Sluder was probably a case of circulatory stasis, which seems to be the condition in a majority of the cases — pressure due to circulatory disturbances.

Afternoon Session at 2.30 p. m., May 4, 1910.

Joint session with the Climatological and Otological Societies at the New Willard Hotel. General topic for Discussion: "Vaccine Therapy."

The Climatological Society represented by Drs. J. A. Miller and J. M. King.

The Otological Society by Drs. H. C. Reik and B. A. Randall; and

The Laryngological Association by Drs. H. S. Birkett, C. G. Coakley, and F. C. Cobb.

Dr. Randall said that the application of opsonic treatment by vaccines to diseases of the ear has been too limited and carried on by too few investigators to have reached definite results. Hardly a hundred individual cases are recorded, and while these are encouraging, especially to enthusiasts, there are too many loopholes for any estimate of them to carry conviction to clear minds. The permanence or uniformity of success which should distinguish a monumental improvement in therapy cannot yet be considered established, while some of the reports are open to suspicion of being none too well posted or else too pessimistic as to the older measures. Closer scrutiny of the instances of its employment will probably give greater confidence in the possibilities of the method, and it was to be hoped that this joint consideration of the subject will serve to crystallize into more available shape its practical applications, and that growing experience will show more frequent realizations of the hopes and claims of the enthusiasts.

VACCINE THERAPY IN OTOLOGY.

By Henry O. Reik, M.D., Associate in Ophthalmology and Otology in the Johns Hopkins University; Surgeon in the Baltimore Eye, Ear and Throat Hospital, Baltimore, Md.

After a summary of what has been accomplished by the use of vaccines in otology and a careful consideration of the various conditions encountered, the author offers the following conclusions and suggestions in regard to the relation of vaccine therapy to otology:

1. The employment of vaccine therapy in otology, although having had but a limited trial so far, has been attended by such successful results as to warrant us in feeling greatly encouraged.

2. Furunculosis, with its recognized tendency to the formation of boils in crops, seems to have responded more promptly and satisfactorily to this form of treatment than to any other, and, in tuberculosis of the middle ear, a condition heretofore so baffling to the otologists, there would seem to be good reason to believe that at last we have a controlling, curative remedy.

3. Looking into the future, we have held out to us the enticing prospect of being able to cure without operation a larger percentage of our cases of persistent, chronic purulent otitis media, or, failing in that, of insuring success for the operative treatment of this affection.

4. The aural conditions to which this new form of treatment would appear to be reasonably applicable are the treatment of chronic suppurative otitis media; the preparation of patients for operation, raising the opsonic index in order to facilitate rapid healing after obliteration of the gross lesions; and the post-operative treatment of mastoiditis and its complications where healing is delayed and the patient is unable to construct new tissue without aid.

5. While the outlook is hopeful in these several directions, we must not grow too enthusiastic as yet. We are perhaps justified in some degree of optimism, but not in enthusiasm. Let us try the method further, with fairness, and judiciously, not expecting the impossible from it, for it will not entirely displace any other form of treatment; no matter how valuable it ultimately becomes, it will only be an additional therapeutic measure at our command.

THE VALUE OF VACCINE TREATMENT OF CHRONIC INFLAMMATORY DISEASES OF THE ACCESSORY SINUSES OF THE NOSE.

By H. S. Birkett, M.D., Professor of Oto-laryngology, McGill University; Oto-laryngologist, Royal Victoria Hospital, Montreal; and J. C. Meakins, M. D., Demonstrator in Clinical Medicine and Pathology, McGill University; Clinical Assistant in Medicine, Royal Victoria Hospital, Montreal.

The history of the application of the principle that immunity follows an attack of certain infectious diseases was sketched from its first recognition by Jenner and the later work of Pasteur, followed by the development of "the cellular" and "the humoral" views of immunity maintained by Metchnikoff and Ehrlich, the reconciliation of these two views by Denys and Leclef, and the demonstration by Wright that the blood plasma contains a substance which must first act upon the bacteria before the leucocytes can ingest them.

The authors claim that chronic and localized infections are eminently suited for vaccine treatment, and after a careful study of the anatomy and pathology of the accessory sinuses of the nose, the application of treatment by vaccine therapy by others and the personal observation of four detailed cases, they reach the following conclusions:

1. Vaccine treatment will sterilize the accessory sinuses of the nose when the subject of chronic disease.

2. The chronic discharge of mucus from the accessory sinuses of the nose is not so much due to bacterial infection as to habit hypersecretion.

3. The symptoms are not due to infection, but to hypersecretion and retention.

4. Although vaccine therapy is a valuable adjunct to treatment, the establishment of free drainage by the removal of polypoid masses and redundant mucous membrane is more important.

5. The cases of sinusitis showing a tendency to become chronic should be treated early by homologous vaccines.

Dr. Cornelius G. Coakley, New York, took a less hopeful view of vaccine therapy than did Dr. Birkett. His results had led him to the following conclusions:

1. The bacterial flora of the sinuses consist of the following organisms: Streptococcus pyogenes, micrococcus albus and aureus, staphylococcus pyogenes albus and aureus and bacillus mucosus capsulatus.

2. The opsonic index has been unsuitable, either as a means of clinical diagnosis or as a criterion for further treatment.

3. That vaccinations made in varying strength have not been followed by those changes in the opsonic index which would be expected were this method of treatment one on which we could rely in practical work.

4. The amount of time necessary to carry out fully a careful opsonic treatment are not only beyond that which the ordinary practitioner could afford to spend, but are, with the present technic and status of the subject, quite out of proportion to the value of the information which one might derive from such procedure.

The therapeutic results of his own cases were, in his own judgment, absolutely worthless. He could not say, on the other hand, that any harm had been done to his patients. Before the use of vaccines, the chronic patients had frequent periods of improvement of their symptoms and periods of aggravation. In a few instances some improvement was noted after the first or second injection, but later the discharge and other symptoms returned as they had done under other plans of treatment.

DR. FREDERIC C. COBB, Boston, had had good results in clearing up chronic ear discharge, but not such good results in nasal cases, although the anatomical conditions, so far as closed cavities draining through narrow openings were concerned, were apparently alike. In a series of atrophic rhinitis cases, however, the results were better. A bacillus of which he could find no description was found in all cases. From it a vaccine was made and injections varying in amount from 150,000,000 to 500,000,000 were given. A very general improvement in odor and amount of crusts and discharge had resulted, yet in no instance could an absolute cure be claimed. Before commencing vaccine treatment these patients were in the habit of using nasal washes, and this treatment was not changed while carrying out the injections except that before periodical examinations they were not allowed to use the douche for twelve hours. The patients themselves were enthusiastic over the results of treatment. Autogenous vaccines seemed to yield better results than stock vaccines. The same general degree of results had followed in sinus cases, that is, improvement, but no absolute cure.

(*To be continued.*)

Book Review.

Hookworm Disease. Etiology, Pathology, Diagnosis, Prognosis, Prophylaxis and Treatment. By GEORGE DOCK, A.M., M.D., Professor of the Theory and Practice of Medicine, Medical Department, Tulane University of Louisiana, New Orleans; and CHARLES C. BASS, M.D., Instructor of Clinical Microscopy and Clinical Medicine, Medical Department, Tulane University of Louisiana, New Orleans. Illustrated with forty-nine special engravings and colored plate. Pp. 250. St. Louis: C. V. Mosby Company. 1910.

In view of the recent recognition that hook worm disease exists in a large part of the United States, and that it is among the most important of diseases in the South, this description of the disease by Dock and Bass deserves wide attention. The disease is believed to have reached Europe from Egypt; its occurrence in Europe has been chiefly among miners, laborers in tunnels, and brick workers. In America an epidemic probably of this disease was described in Brazil in 1648; the earliest mention of it in the United States was in 1808. The parasite was first described in 1782 in animals, but was not connected with the disease in man until 1853, and its connection with human anemia first received general recognition in 1877. Ashford, in 1899, showed the great prevalence of hookworm infection in Porto Rico, and Stiles, in 1901, showed it to be widespread in the United States. Stiles further demonstrated that the American hookworm was a species distinct from that of the old world, which, however, also occurs in America.

The parasite requires for its growth high temperature and moisture. The disease is, therefore, one of southern regions and of deep mines. It occurs mainly among those who have intimate relations to the soil, particularly those with bare feet. The biology of the parasite is minutely described. Of great interest and importance is the demonstration of the mode of entrance to the human body, not as was formerly supposed by the alimentary tract, but through the skin. This process is accompanied by the symptom familiarly known as "ground itch."

The pathology of the disease is chiefly that of anemia and the resulting abnormalities of oxygen metabolism. It is possible, however, that the lack of development, when the disease occurs in early life, may be due not so much to the anemia as to the local lesions in the intestine.

The symptoms are variable and may be slight or absent. Most common is this very mild form of the disease where symptoms are not noticed; the chief importance of these cases is as carriers of the parasite. Next most common is the type of disease classed as mild, manifested by moderate pallor and anemia, and lowered vitality and energy, and in children somewhat impaired growth. The third type is the severe type where the anemia, weakness, dyspnea, edema and impaired growth are too marked to be overlooked. This type is relatively rare in the United States, but in Porto Rico has caused a large percentage of all deaths in the island.

The diagnosis rests chiefly upon the demonstration of ova in the stools; the process of examination for these is, therefore, minutely described. Eosinophilia of over 8% has been shown to occur in the blood of 94% of cases.

Much stress is very properly laid upon the prophylaxis of the disease under three headings: (1) the extermination of the worms in human carriers, even those without symptoms; (2) the prevention of dissemination of larvæ by the invariable use of proper privies; and (3) education in precautions against infection.

To remove the disease the thymol treatment properly carried out has proved extremely effectual.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, DECEMBER 22, 1910

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 809 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 Tremont Street, Boston, Mass.

READING FOR PHYSICIANS.

Medicine has long been known as one of the learned professions, and physicians have been looked to as wise men, not only in the care of the sick, but in a broad general knowledge of literature,— and of scientific literature especially. The earlier generations had such literary knowledge, because knowledge of medicine implied knowledge of old authorities. Moreover, a few years ago the total available literature of medicine was small compared with what we now know. Then there was the occasional physician, like Arbuthnot, or Brown, or Holmes, who contributed to general literature, and helped by such contributing to impress the public with a sense of the wide interests of physicians.

We have changed all that. We are no longer a learned profession in the old sense, — rarely as individuals are we widely learned. In the aggregate, however, our knowledge of nature and of her processes is incomparably greater than formerly it was. Special students of special problems have worked out the grand total of present knowledge. In spite of specialism, however, and the fumbling prophecies of a few years back, general practitioners still flourish among us. They are mostly earnest, over-worked men, well educated so far as that is possible in these complicated times; and they struggle to keep abreast of multitudinous progress. They struggle vainly. No man can gather and digest all the new things. The general practitioner, the general medcal reader, is in a state of intellectual dyspnea. The hard routine of his daily round and the collecting of his fees is exhausting enough, but he is asked in addition to keep elaborate bedside notes, to execute numberless laboratory tests, to consult specialists, to subscribe to a half dozen medical journals and compendiums of practice, and to buy the new books. Especially must he take the journals and the books, he is told; otherwise will he be put to shame before his fellows, and soon be classed as a back number. These are grievous obligations. They are impossible. No general practitioner meets them. If he makes the claim, pass him quickly by, for he tries to deceive you. Vast numbers of toiling practitioners, however, endeavor to meet these impossible demands. Go into the office of a busy practitioner; you will find his table loaded with unopened mail — journals months old; and his bookshelves lined with volumes which presumably he will never read.

The remedy is easy and obvious. He needs a few, not many, good journals. Several good, standard, up-to-date journals will give him a speaking acquaintance with progress. These he will read at least in part. He should buy those books only which are favorably *reviewed* in a responsible journal. The art of the honest reviewer fortunately is not yet dead.

Let us then take heart and fresh counsel; and let us believe that opportunities for learning still linger among us, if only our energies be kept unimpaired and our efforts be directed toward a definite end.

PREVENTION OF ABUSE OF MEDICAL CHARITY.

A circular is at hand, issued by the committee of the Chicago Medical Society on the abuse of Medical Charities, relating to the movement in Chicago for the regulation and improvement of institutional medical charity. This movement, which has already excited considerable interest throughout the country, aims at correcting economic abuses in hospital administration, improving the service to the poor in free institutions, and preventing the hospitalization of members of the community who are not deserving objects of medical charity. The widespread abuse of such charity is well known, and medical pauperization is its inevitable result. To check this abuse, the committee proposes the establishment of a headquarters of investigation, where every applicant for free institutional medical charity should undergo thorough inquiry and scrutiny, which will be carefully and permanently recorded. The project, which is to be supported at first by private subscription, deserves enthusiastic encouragement by the profession. Demonstration of its successful application should be followed by its adoption in other similarly situated communities.

ADVANCING STANDARDS OF MEDICAL EDUCATION.

THE effect of raising the standard of medical education is well illustrated by the recent experience of the University of Michigan. Two years ago its medical department established the entrance requirement of at least two years of previous collegiate study. The number of students in the entering medical class immediately fell from 144 in 1908 to 36 in 1909. In 1910, however, the number has risen to 58. This is precisely what was to be expected, nor should the advocates of increased efficiency of medical education be discouraged thereby. In every walk of life the individual must either meet the demands of the advancing civilization which is his environment or else go to the wall. In medicine, therefore, physicians must be continuously more highly trained than heretofore. Such specialization will mean, as it does everywhere else in nature, diminution in number but increase in efficiency of the survivors. The result will be a gain to the community and to the dignity and progress of medical science.

INTERNATIONAL OPIUM CONFERENCE.

INTELLIGENCE from Washington, D. C, states that plans are completed for an international opium conference at the Hague on May 30, 1911. The countries to be represented are the United States, China, Great Britain, France, Germany, Italy, Japan, The Netherlands, Persia, Portugal, Russia and Siam. The conference will deal with the problem of cocaine and morphine, as well as that of opium. The extent of the illicit traffic in these drugs, and their illegitimate use, is hardly realized by the respectable public. In the year 1909, 185,000 oz. of cocaine were imported into the United States, of which only 5,000 were used for legitimate medical purposes, the remainder being consumed by habitués. Of the 75,000 lb. of opium brought into this country annually, probably over three fourths are employed by opium smokers and eaters. The suppression of such vices in civilized countries should be far easier than to check the improper use of alcohol, and positive results towards this end may be hoped from concerted action following the opium conference next spring.

MEDICAL NOTES.

ABATEMENT OF BUBONIC PLAGUE IN MANCHURIA. — It is reported from St. Petersburg that there is a marked abatement of bubonic plague in Manchuria and that no new cases of the disease had occurred in that country during the three days ending Dec. 15.

AWARD OF THE LA GRANGE PRIZE. — It is reported from Brussels that on Dec. 15 the Royal Academy of Belgium awarded the Charles La Grange prize in physics to Dr. L. A. Bauer, director of the department of terrestrial magnetism at the Carnegie Institution, Washington, D. C.

RELATION OF COMPLEXION TO TROPICAL DISEASE. — An investigation is said to be in progress by a board of United States army surgeons as to the relative susceptibility of persons with light and with dark complexions to heat-stroke and various tropical diseases. *A priori* it should seem that brunettes should be more tolerant of insolation than blondes, but immunity to infections would hardly seem likely to be affected by such a factor.

PURE MILK AND INFANT MORTALITY. — The value of a pure milk supply in cutting down infant mortality is well illustrated by the percentage of deaths under one year of age in Berlin. In the decade from 1870 to 1880 this figure was 30%; from 1880 to 1890, it was 27.1%; from 1890 to 1900, 23.2%; from 1900 to 1910, only 19%. This reduction, though doubtless due in part to other factors, has taken place *pari passu* with the extension of the system, begun in 1880 by the philanthropist Bolle, of supplying good milk to the poor at moderate price.

AMENDMENTS TO THE ROCKEFELLER FOUNDATION BILL. — In a recent issue of the JOURNAL we referred to certain objections that had been raised to the federal incorporation of the Rockefeller Foundation. To meet these objections, several amendments have been made to the bill for the chartering of the foundation, now before Congress, giving the government a voice in the selection of the trustees, requiring the annual distribution of the entire income and limiting the total amount of the fund at any time to $100,000,000. It is hoped that with these restrictions there may be no further opposition to the establishment of the foundation.

A PROLIFIC FAMILY. — Report from Richmond, Ind., states that Mrs. Jason Bonner, of New Castle, Ind., has recently given birth to her twenty-eighth child. Of her large family of offspring, twenty-one are at present living.

Mrs. Bonner is now forty-five years of age and her husband forty-nine. It is not stated how long they have been married.

The Typhoid Epidemic at Annapolis. — During the week ending Dec. 17 only one new case of typhoid fever was reported at the United States Naval Academy at Annapolis, Md., making a total of 30 patients now under treatment for the disease. There have as yet been no deaths, though one cadet is stated to be critically ill. A commission of four naval surgeons has been appointed by the Secretary of the Navy to make further investigation and official report as to the probable cause of the epidemic.

Two Centenarians. — Mrs. Elizabeth Shoemaker, who died on Dec. 16 at her home near Dupois, Pa., was locally reputed to have been born in 1806. She is said to have retained her physical and mental vigor until a very short time ago.

Dinah Hicks, a negro nurse, who died last week at New Rochelle, N. Y., was alleged to be one hundred and ten years of age. She was born a slave in Virginia. For the past thirty years she had lived in the family of a justice of the supreme court.

An Apparatus for Inhalation of Alcohol. — Unofficial report from London describes the invention, by Dr. Leonard Erskine Hill, of an apparatus providing for the inhalation of a mixed vapor of oxygen, water and alcohol. This apparatus, which is intended for use in the treatment of pneumonia, is based on the theory that in this way stimulation may be supplied to the heart better than by the route of gastric absorption. The soundness of this theory and the efficacy of the apparatus remain to be tested by experience. It would seem that this method might be open to the objection of the irritant action of alcohol on diseased or susceptible lung tissue.

Progress of the Cholera Epidemics. — During the week ending Dec. 17, 22 new cases and 7 deaths of Asiatic cholera were reported from Italy, as against 29 cases and 11 deaths the preceding week.

Report from Funchal, Madeira, states that the cholera epidemic in that island is still active. At Santa Cruz, on Dec. 15, a number of arrests were made of rioters who resisted the measures taken by the government to check further spread of the infection. This action illustrates the difficulty experienced by preventive medicine in making headway against popular ignorance and superstition, a difficulty not confined solely to countries with a population of primitive or uncivilized inhabitants.

Dr. Osler's Challenge to the Anti-Vaccinationists. — In an article in the *American Magazine*, on the service to the community of the control and abatement of disease and pain by medical science, Dr. William Osler says in consideration of the value of vaccination: "A great deal of literature has been distributed casting discredit upon the value of vaccination in the prevention of smallpox. I do not see how any one who has gone through epidemics as I have, or who is familiar with the history of the subject, and who has any capacity left for clear judgment, can doubt its value. Some months ago I was twitted by the editor of the *Journal of the Anti-Vaccination League* for 'a curious silence' on this subject. I would like to issue a Mount Carmel-like challenge to any ten unvaccinated priests of Baal. I will go into the next severe epidemic with ten selected vaccinated persons and ten selected unvaccinated persons. I should prefer to choose the latter — three members of parliament, three anti-vaccination doctors, if they could be found, and four anti-vaccination propagandists. And I will make this promise — neither to jeer nor to jibe when they catch the disease, but to look after them as brothers, and for the four or five who are certain to die I will try to arrange the funerals with all the pomp and ceremony of an anti-vaccination demonstration."

Boston and New England.

Acute Infectious Diseases in Boston. — For the week ending at noon, Dec. 20, 1910, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 35, scarlatina 32, typhoid fever 6, measles 36, smallpox 0, tuberculosis 45.

The death-rate of the reported deaths for the week ending Dec. 20, 1910, was 17.49.

Boston Mortality Statistics. — The total number of deaths reported to the Board of Health for the week ending Saturday, noon, Dec. 17, 1910, was 217, against 215 the corresponding week of last year, showing an increase of 2 deaths and making the death-rate for the week 16.79. Of this number 118 were males and 99 were females; 212 were white and 5 colored; 122 were born in the United States, 93 in foreign countries and 2 unknown; 40 were of American parentage, 148 of foreign parentage and 29 unknown. The number of cases and deaths from infectious dis-

cases reported this week is as follows: Diphtheria, 36 cases and 4 deaths; scarlatina, 33 cases and 1 death; typhoid fever, 2 cases and 2 deaths; measles, 26 cases and 1 death; tuberculosis, 62 cases and 24 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 34, whooping cough 2, heart disease 19, bronchitis 3. There were 11 deaths from violent causes. The number of children who died under one year was 29; the number under five years 46. The number of persons who died over sixty years of age was 67. The deaths in public institutions were 85. Cerebrospinal meningitis, 1 case and 1 death.

Of the above infectious diseases the following were non-residents: Consumption, 2 cases. Scarlet fever, 2 cases. Diphtheria, 2 cases and 1 death. Measles, 1 death.

Deducting deaths of non-residents, the total is 202 and the death-rate is then 15.63.

DIPHTHERIA AT BEVERLY. — Two new cases of diphtheria were reported last week among pupils at the Beverly Farms (Mass.) Grade School, as a result of which the school was temporarily closed. This is the second time during the present session that the school has been closed on account of diphtheria. The building will be thoroughly disinfected before being reopened.

SCARLET FEVER IN QUINCY. — A minor epidemic of scarlet fever is in progress at Quincy, Mass. Twelve cases among schoolchildren have been reported, nearly all traceable to infection from a single family. The local board of health has ordered the school in which the cases occurred closed indefinitely, and has also directed the meetings of the various Sunday-school classes to be suspended for at least a fortnight.

MILK COMMISSION, SUFFOLK DISTRICT MEDICAL SOCIETY. — The Suffolk District Medical Milk Commission, starting Jan. 1, 1911, will be as follows:

Dr. James Marsh Jackson, 230 Beacon St., Boston, chairman; Dr. George A. Craigin, 18 Hereford St., Boston; Dr. Robert L. DeNormandie, 357 Marlborough St., Boston; Dr. B. L. Arms, 30 Huntington Ave., City Bacteriological Laboratory; Dr. Fritz B. Talbot, 311 Beacon St., Boston; Dr. Richard M. Smith, 222 Marlborough St., Boston, secretary.

A LIVING CENTENARIAN. — Mrs. Polly Johnson, of East Somerville, Mass., who is said to have been born on Dec. 16, 1810, at Malone, N. Y., celebrated last week the supposed centennial anniversary of her birth. She has four children and four grandchildren surviving. Her health is excellent, and she attributes its persistent vigor to her lifelong habit of rising at six o'clock in the morning.

CHRISTMAS CELEBRATION OF THE INDUSTRIAL SCHOOL. — The annual Christmas celebration of the Industrial School for Crippled and Deformed Children will be held at the institution building on Friday, Dec. 23.

BEQUEST TO QUINCY HOSPITAL. — Among several charitable bequests in the will of the late Peter B. Turner, of Quincy, Mass., filed for probate last week at the Norfolk Probate Court, was one of $100 to the Quincy City Hospital.

NEW ENGLAND ALUMNI OF NEW YORK MEDICAL COLLEGE. — The eighth annual meeting of the New England Alumni Association of the New York Medical College was held last week in Boston. Among the guests and speakers was Dr. William M. Polk, of New York City. Dr. Elgin W. Jones, of Lynn, Mass., was elected president of the association for the ensuing year; Dr. J. Henry Woods, of Brookline, Mass., secretary; and Dr. James H. Stuart, of Boston, treasurer.

PENALTIES FOR VIOLATION OF PURE FOOD LAWS. — Last week a farmer living near Ware, Mass., pleaded guilty before the local district court to the charge of watering the milk sold from his dairy. Another dealer of the vicinity had his license revoked for repeated violation of the milk rules.

Before the municipal court in Boston last week a dealer from Littleton, Mass., was fined $100 for selling to a wholesale firm a carload of adulterated vinegar.

TUBERCULOSIS EXHIBIT AT CHICOPEE. — The local board of health at Chicopee, Mass., has recently accepted from the tuberculosis committee of The Massachusetts Medical Society the loan of a tuberculosis exhibit for use in the Chicopee public schools. The exhibit consists of large wooden frames in which are photographs illustrating conditions conducive to consumption and methods for its prevention. Its showing will be accompanied by an explanatory lecture by a member of the board of health. The value of these loan exhibits in the education of the public as to the nature and avoidability of tuberculosis is believed to be very great.

Expectoration and Concealed Weapons. — The prosecution of the campaign in Boston against promiscuous expectoration continues, though with somewhat abated vigor. Every prisoner arrested for spitting is searched as a routine, and one of the interesting revelations of the process has been the number of concealed weapons discovered. The apprehension of these is much more lucrative to the government than conviction for spitting, since the fine for carrying a loaded revolver is $25; that for expectoration, not more than $5. Under certain circumstances, however, the prevalence of the latter habit is likely to be far more dangerous to the community than the former.

NEW YORK.

Health Conditions. — Notwithstanding the unfavorable conditions incident to its multitude of tenement houses with their congested population, the health of the city of New York is at present better than that of the rural portion of the state. In the month of October the death-rate in New York was 14.0, while in the non-urban population it was 15.8. In the other cities of the state the death-rate was 14.7. In October of last year the urban death-rate was 15.6, and the rural, 16.2.

A Fund for St. Mary's Hospital, Hoboken. — The committee organized to obtain a thanksgiving fund for St. Mary's Hospital, Hoboken, in token of the appreciation of the citizens of New York for the care given by the sisters in charge of the hospital to Mayor Gaynor after the attempt on his life last summer, presented the fund to the sisters on Dec. 18. The total amount was $15,184, and was handed to the sister superior in the form of two checks, one for $5,000 and the other for $10,184. The $5,000 check is to endow a bed in honor of the mayor, while the rest of the money is to be expended at the discretion of the sisters. The presentation was made by John D. Crimmins, chairman of the committee, who was followed by Corporation Counsel Archibald R. Watson, representing Mayor Gaynor, and the gift was accepted by Father Ahne on behalf of the sisters. A letter was also read from the mayor, in which he expressed his regret at not being present, stating that he had to be out of town at the time for the benefit of his health.

Bequests. — Among other charitable bequests in the will of the late Isaac Stern, a prominent New York merchant, are $10,000 to Mount Sinai Hospital and $4,000 to the Montefiore Home and Hospital for Chronic Invalids. During his lifetime also Mr. Stern was a liberal contributor to these and other Jewish charities.

Subscription for American Red Cross Society. — New York City has now completed its subscription of $500,000 for the American Red Cross Society, the amount of the proposed $2,000,000 endowment fund which was apportioned to it on the basis of 10 cents per capita of the population.

Ancient Hebrew Sanitation. — The public lecture at Columbia University on Dec. 5 was by Dr. D. C. Pease, sanitary expert of the Board of Water Supply, on "Insect Carriers of Disease," and in the course of it he made the statement that the many burnt offerings and sacrificial ceremonies of the ancient Hebrews were designed with a practical view to exterminating the fly and other insect pests from the meat of slaughtered cattle.

Laboratory for Examination of Chemicals. — At the opening of the meeting of the American Institute of Chemical Engineers, on Dec. 7, John Purray Mitchell, president of the Board of Aldermen, in an address welcoming the members of the institute to the city, announced that it had been decided by the municipal authorities to establish a fully equipped laboratory for the examination of all chemicals purchased by the city, to be managed by a board of directors of the highest professional standing. This step has been urged for some time, as the present public laboratories are not equipped to do the work satisfactorily, and the city often pays a high price for poor material. With such a laboratory, managed in the manner contemplated, such a thing as graft or favoritism in the granting of contracts would be practically impossible.

Damages for Loss of Life. — After lengthy negotiations the New York Central Railroad and the estate of Spencer Trask have come to an agreement in regard to the damages to be paid for the loss of the financier's life in a railway accident on Dec. 31, 1909. The amount settled upon is $60,000, the largest sum ever known to have been paid by a railroad corporation for the death of a passenger, and the award is based on the value of the deceased's personal relations with his various and extensive business undertakings. The widow's share is $32,000, and it is announced that of this amount, $24,000 is to be given by her to the village of Saratoga Springs as "a fitting dedication of the money to the town to which Mr.

Trask devoted many years of zealous service, and for which in the end he sacrificed his life." The remaining $8,000 she presents to the Bethesda Protestant Episcopal Church, at Saratoga, to complete Mr. Trask's gift of a parish house.

DETECTION OF A MALINGERER. — Mrs. Anna Strula, who had been on trial for two days in the Court of General Sessions, charged with swindling the New York Central Railroad out of $500, pleaded guilty on Dec. 2 before half the prosecution's witnesses had testified. She admitted that in less than four years she had received more than $5,000 damages from seventeen railroad and steamboat companies by claiming to have been injured through the carelessness of their employees. The woman had pleaded guilty to the same charge two weeks previously, but, after being told that the judge would grant her no leniency, she decided to stand trial. A number of physicians who had examined her at the time she made the claim against the New York Central expressed the opinion that the injuries she alleged she had received from a fall at the 125th Street Station were not caused by the fall. In nearly all the claims made by her the cause of her slipping and falling was a banana skin. This won for her the title, "the banana-peel artist," and she actually had a bag filled with the skins when she was arrested.

MEETING, SOCIETY OF MEDICAL JURISPRUDENCE. — At the annual meeting of the Society of Medical Jurisprudence, held on Dec. 12, the following officers were elected: President, Alfred E. Omman; Vice-President, Reynold Webb Wilcox, M.D.; Recording Secretary, Oscar W. Erhorn; Correspondng Secretary, Charles P. Blaney; Treasurer, John C. West. The subject of the evening's discussion was the abuse of the writ of habeas corpus in freeing insane persons dangerous to the community and to themselves, and a resolution was adopted recommending an amendment of the criminal law to the effect that criminals who are now "acquited because insane" should be adjudged "guilty, but insane." A committee was also appointed to confer with a similar committee from the State Bar Association, with a view to securing the proposed change by the action of the legislature. Addresses on the discharge of lunatics by habeas corpus proceedings were made by Frederick A. Fenning, of the Washington bar; Dr. William A. White, superintendent of the Government Hospital for the Insane at Washington; and John Brooks Leavitt, LL.D., chairman of the committee on the commitment and discharge of the criminally insane of the New York City Bar Association. In the course of his remarks the last-named said: "Our struggle in this state is, not to keep insane men from getting out of, so much as to keep sane men from getting into, the asylums, in order to escape the penalty of their crime. . . . Whip these facts into a hypothetical question, pay a heavy medical fee for a specialist to frame it, let him swear the client into insanity and six months later jauntily swear him out, and the criminal escapes scott free, except for the fees! . . . The crime has been done and it makes no difference to society if it has been done by a lunatic or a sane man; and, as a protection to society, the criminal, sane or insane, must be confined. Then let his lawyer, in that little private consultation after the murder, bid his client choose alternatives: 'If you want to be insane, you will be locked up for life. If you want to be sane, you will be hanged. Now choose.' Then there will be no large legal fees and no large medical fees, and no one will be the worse except the lawyers and doctors."

6. SCHIEMANN, H. *Carbolic Acid Injections in Piles and Goiter.*
7. SALLOM, A. K. *Preliminary Report of a Statistical Analysis of over Thirty-two Thousand Cases of Scarlet Fever.*

4. From investigations extending over three years, Schultze is convinced that the danger of infection in scarlet fever lies more in the throat and nasal passages than in the scales of desquamation. He has examined thousands of cultures taken from the pharynx in patients clinically ill with this disease, and in about 80% of them he has demonstrated a large coccus, which stains very deeply with Löffler's alkaline methylene blue. He has recovered micro-organisms morphologically identical with this coccus from blood, skin and aural pus of scarlet fever patients. He, therefore, urges the importance of early bacteriologic examination of the nasopharyngeal secretion in all non-diphtheritic sore throats. [L. D. C.]

9. Goldsmith, M. *A Case of Hepatic Syphilis.*

5. Clowe believes that acute primary polymyositis is a clinical entity. The early symptoms are malaise, weakness and indefinite pains in various parts of the body. Later the limbs become edematous and cyanosed, the subcutaneous tissues swollen and the skin cold. When the edema subsides the muscles are tender and have a hard, doughy feel. Soon after this contractures appear and finally the muscles atrophy. The extremities are affected first, then the chest, abdomen, neck and throat. There is no involvement of nerves.

This disease is probably infectious. It is most likely to be confounded with multiple neuritis and trichinosis, and may simulate rheumatism, typhoid fever and osteomyelitis. The prognosis is not good. Attacks are often fatal, the greatest danger being involvement of the myocardium or of the muscles of deglutition. Permanent disability is to be expected in most cases. [L. D. C.]

1. Anders considers that vaccine therapy in the very acute stages of typhoid may be dangerous. It is, however, valuable, as a means of prophylaxis, to prevent relapses in the convalescing stages, to combat local infections with the typhoid bacillus, as in bone suppurations, and for the removal of typhoid bacilli from typhoid carriers.

4. Miller summarizes his observations on the use of alcohol in acute infections as follows: The impairment of the vascular regulating mechanism is more apparent than active disturbance of the heart. Alcohol in small amounts acts as a cardiovascular stimulant, but larger amounts in individuals not addicted to its use invariably act as cardiovascular depressant by paralyzing the vasomotor center. It is not possible to determine the amount in each case which will act as a stimulant rather than as depressant, and hence the drug is unsafe to use in most cases.

5. Boos summarizes his observations on magnesium poisoning as follows: Magnesium sulphate in bulk or in concentrated solution is absorbed, in part at least, from the gastro-intestinal tract into the blood. If a sufficient amount is absorbed in a given time, poisoning will result; of ten cases reported, six resulted fatally. The symptoms and autopsy findings agree very well with those obtained in animals after the intravenous use of this drug. On account of the slowness of excretion from the system, magnesium sulphate may produce poisoning from its cumulative effect if given repeatedly in concentrated solution; this is particularly true in obstructive cases. Large doses of normal saline solution given intravenously are the antidote. The subcutaneous use of this drug to produce catharsis as proposed by Wade is not only absolutely irrational, but dangerous.

8. Elsner speaks as follows of Ehrlich's new remedy for syphilis, "606": The spirochete pallida is positively destroyed and the living contagion of syphilis is promptly removed by this drug. It promptly affects visible and palpable syphilitic lesions and removes deep-seated gummata; it stays the destructive ulcerations and causes their healing in a surprisingly short time; it is more rapid in its effect on specific disease than any other known remedy. It cannot replace cicatricial tissue, nor can it affect chronic degenerative conditions of the nervous system. In all cases it causes a leucocytosis and the formation of antibodies. It materially modifies and in most cases ultimately negatives the Wassermann reaction. It unquestionably floods the circulation with endotoxins resulting from the death of millions of spirochete, and in all probability an antitoxin is developed in the blood serum. It ought not to be given to ambulatory patients. Patients receiving "606" should be kept in bed seven days under close observation. Second injections should not be given less than eight weeks after the first. Patients with any other infection besides the present syphilis should not be injected. [E. H. R.]

11. *Ross, G. C. *Retention Cysts of the Kidney.*

1. Magnus-Levy's article is an exhaustive discussion of the theories of the pathological physiology of gout, concluding that in the present state of our knowledge we are forced to the belief in a retention of uric acid due to damaged function of the kidneys as the only solution of the problem. The many objections to this theory are, however, fully pointed out, and our lack of positive evidence is made plain. In treatment it is shown that colchicum and salicylate have an opposite action, the latter materially increasing the excretion of uric acid while the former does not increase it and may diminish it. It is suggested that while colchicum has seemed more effectual in affording immediate relief, the use of salicylate may in the long run prove more desirable. The use of alkalies is regarded as theoretically undesirable. Falkenstein's hydrochloric acid treatment is recommended for further trial.

2. James and Williams publish the second division of their report on the use of the electrocardiogram, containing a description of findings in cases where the muscular action of the heart is abnormal. Their records show the curves obtained in hypertrophy, in sinus irregularity, in extrasystoles, both auricular and ventricular, in absolute arrhythmia and in digitalis heart block. The tracings in absolute arrhythmia are of chief interest since they show waves believed to be due to fibrillation of the auricle, but give no evidence of the late contraction of the auricle which Mackenzie has described in such cases, and, therefore, throw doubt upon Mackenzie's theory of the nature of this

irregularity. It is to be regretted that the electrocardiogram is so complicated and expensive that it cannot be more generally employed, since work such as has been carried out by James and Williams gives promise of important advances.

3. Brem and Zeiler, of the Colon Hospital, Canal Zone, report that, after discouraging experience in the treatment of amebic dysentery by other methods, the ipecac treatment gave complete success in all of eight cases followed from six weeks to five and one-half months, and in three other cases followed for a shorter period. The use of salol-coated pills seems to have been essential to success, since it was impossible to give sufficient doses of ipecac except in these without causing violent vomiting. A salol coat one-sixteenth inch thick seemed best to insure both against solution in the stomach and against failure to dissolve before expulsion from the colon. The best method of administration seems to be to give 60 or 80 gr. at bedtime on the first night and to diminish the dose by 5 gr. each night until a dose of 10 gr. is reached, after which it is discontinued and a permanent cure may be expected. The patient should be at rest in bed and on liquid diet. No milk or solid food should be given for at least six hours previous to the ipecac, and no liquids for three hours before it.

4. Skinner's article is a careful description of the measures which he employs in the treatment of arthritis deformans, or atrophic arthritis. Recognizing as possible etiological factors (1) trophoneurosis, (2) infection, (3) autotoxemia, and (4) depressed cerebrospinal function as result of systemic toxemia from any cause, or possibly abnormal function of ductless glands, he considers as chief therapeutic indications (1) to close possible avenues of infection; (2) to improve general and local nutrition; (3) to accentuate elimination of katabolic products; and (4) to limit the formation of autotoxins. The measures by which he aims to improve general metabolism and body function, the general hot-air bath, electricity in various forms, hydrotherapy, are described in detail. The routine application of the treatment to the individual case is as follows. Rest in bed for at least ten hours out of twenty-four. Diet, generous, but with avoidance of excess of meat or fish. Strychnine and iron before meals, cod-liver oil after meals. Mineral water before breakfast, if needed for constipation. Hot-air bath, central galvanization, vibration and hot and cold douche, each one to three times a week. Static electricity to affected joints at least once daily; high-freqeuency currents may replace some static applications. For relief of pain, baking or ice-cap or cold compresses covered with oiled silk may be tried. Bier's hyperemia is not recommended. Salicyl compounds may give relief. In nocturnal pain induced by muscular spasm, strontium bromide is useful. In the acute stages rest is to be enforced; later, gradually increased passive and active motion are to be instituted, but forcible manipulations with the idea of breaking up adhesions have been shown by clinical experience to be harmful in these cases. Emphasis is laid upon the importance of instituting treatment in the earlier stages of the disease.

5. Pool calls attention to the occurrence in tetany of contractions in muscles of the leg or arm induced by positions which stretch the sciatic nerve or the brachial plexus, appearing in about one and one-half minutes after the beginning of the test. Since the author first described these phenomena in 1907, others have independently observed them. It is urged that their occurrence be further studied as of possible value as a clinical sign.

6. Landis and Mumford have collected 70 cases in which cardiorespiratory murmurs were heard, not as a result of severe exercise; 45 of these cases were tuberculous. Of 31 cases where a subclavian murmur was heard, 20 were tuberculous.

7. Allyn, from a study of 63 cases of valvular heart disease, observed over long periods up to twenty years, concludes that the prognosis in valvular disease in private practice is much better than is generally realized. The mere existence of a lesion in one who leads a temperate life with well-regulated activities may never cause symptoms. It is only when enlargement and subjective symptoms appear that the prognosis is to be considered grave.

8. Hall's article is an analysis of fifty-two cases of intestinal obstruction, with a brief discussion of findings. It is of value as a review of the subject, but reveals no notable novelties.

9. Weisenburg and Müller call attention to the disease of circumscribed spinal serous meningitis and emphasize the importance of its early recognition, since operation may give complete relief, whereas if the condition is not recognized, an inoperable tumor of the spinal cord is usually supposed to exist. The symptoms closely resemble those of tumor, but differ in their slower development and wider range of involvement, not so definitely localized to nerve root distribution, and, perhaps most important, in a variability in sensory and motor findings at different examinations. A case is reported in detail with successful operation.

11. Ross's article would more properly be entitled "Hydronephrosis," a term more commonly applied to the condition which he describes and which he himself applies to it in the text. The various causes are discussed and three cases are reported. Contrary to common teaching, and without discussion, he mentions complete as well as partial obstruction of the ureter as a cause. [F. W. P.]

6. Rhein reports his observations on the pathology of the spinal meninges of 17 cases of tabes dorsalis, the cortical meninges of 16 of these, and the radicular nerves of 8 cases of tabes and 1 of syphilis of the nervous system. He believes that syphilis, either of the organs, skin, bones or central nervous system and tabes may occur as independent processes at the same time and in the same individual. His chief conclusions are: (1) The radicular nerve lesion is not constant in tabes dorsalis; (2) meningitis is not constant in all stages of tabes dorsalis; (3) lesions of the posterior columns in cases of tabes dorsalis complicated by syphilis do not differ from those found in cases in which there is no evidence of syphilitic lesion; (4) syphilitic meningitis implicating the radicular nerves in cerebrospinal syphilis may exist without causing the characteristic tabetic spinal-cord lesion; (5) the meningitis in some cases of tabes is typically specific in its appearance, but differs in degree in some and is not present in all cases; (6) the cerebral meninges were infiltrated with round cells in all the cases studied; (7) "Rand," or border degeneration, is present in a certain proportion of the cases. [G. G. S.]

THE LANCET.

2. Williams, Evans and Glynn report in detail a case of multiple myeloma with the so-called "Bence-Jones" protein in the urine. The autopsy report is given in full. As cases of this nature are rare, a complete and careful case report is of value.

4. McElroy reports three cases of pulmonary tuberculosis, in one of which an apparent cure and in two remarkable progress resulted from daily intravenous injections of formaldehyde and chinosol for over a month; 50 ccm. of a 1:2,000 solution of formaldehyde plus 1:4,000 solution of chinosol were injected into the median basilic vein. The strength of the solution was gradually increased up to 1:500 in the case of formaldehyde and 1:1,000 in the case of the chinosol. Chinosol is a quinine potash preparation and a powerful germicide. [J. B. H.]

4. The writers believe that radium is likely to prove of great service, both in the treatment of external diseases of the eye and in those of the eyelids. The method of application is simple. The eye is first cocainised and the radium contained in sealed glass tubes, allowing only beta and gamma rays to escape, was applied directly to the affected part. They have experienced absolutely no ill-effects, nor has there been any increase of inflammation or symptoms with the exception of pain which was not severe. The frequency of exposure depended entirely on the progress of the individual case. Their cases were divided as follows: Ulceration of the cornea; non-ulcerative acute inflammations of the cornea and sclerotic; affections of the lids and corneal scars. They give their results in the form of an elaborate table.

6. In the first of the papers here presented, Houston discusses soil, air, defective drains, sewer gas, and water as factors in the spread of disease, with special reference to typhoid; Lents describes the organization and results of the typhoid campaign in southwest Germany, and Bainbridge and O'Brien discuss the distribution of certain bacilli of the food-poisoning group.

7. Macalister, speaking on the subject of dysentery carriers, concludes (1) that healthy carriers are very rare and of no importance and that (2) actual carriers are to be found among the incomplete convalescents, which form a high proportion of the cases.

8. Arkwright describes a series of cases of diphtheria carriers. He places them in three classes: (1) convalescents; (2) "contacts," those who have never had the disease, but who have been in contact with a case of diphtheria or another contact. The large majority of healthy carriers soon lose the bacilli. He mentions another class of carriers, those who have the disease in chronic form without constitutional symptoms. These are particularly dangerous in spreading disease, as they retain virulent bacilli for a long time. As regards treatment, antitoxin is of no value when given subcutaneously. Operative treatment on the tonsils, usually the seat of infection, is the best method of treatment. Gargles are of little value. He speaks of a certain number of strains of bacilli which culturally and morphologically are diphtheria organisms, but are non-virulent to man and to guinea pigs.

13. Ruffer and Willmore discuss the preparation of polyvalent antidysenteric serum and monovalent serum, the biochemical properties of these serums, the differential diagnosis of dysentery by laboratory methods and a summary of the results of the treatment of one hundred and thirty-eight cases of dysentery during the present year, with a comparison of the mortality rate of cases before and after the introduction of the serum treatment. [J. B. H.]

1. These authors present a long article on the question of the treatment of fracture by means of extension bandage apparatus. They describe in considerable detail, accompanied by clear drawings, their method of setting fractures of bones of all extremities and the manner in which the extension is applied. They conclude with the following rules in regard to plaster bandages: Only use them in cases for transportation, in certain complicated cases where a firm bandage is expecially indicated, and in delirious patients. They are to be used in certain cases to be treated in an ambulatory manner and after operation on simple fracture, but in both these cases they must be applied so that they can be readily removed.

4. These authors wish to report on the use of albumen-free tuberculin preparations and to correct an error which appeared in a former number (No. 38) of this journal, which resulted in the mixing up of an endotoxin preparation with Koch's albumen-free tuberculin. They consider the endotoxin recommended by Gordon in this paper as an inferior tuberculin preparation and lacking in specific effect. Koch's albumen-free tuberculin is an entirely different and more effective substance. [C. F., Jr.]

1. The writers report with tables a large number of Wassermann tests. They reach the conclusion that the Wassermann reaction on the corpse behaves as it does in the living, and that it is of some diagnostic value, but that when the pathological examination of lesions leaves doubt as to their origin, a positive Wassermann test does not justify the inference that such lesions are syphilitic.

2. Spiegel tried the v. Dungern modification of the Wassermann reaction on a large number of cases, syphilitic and non-syphilitic, and believes that it is of practical value for the diagnosis of syphilis. His results compare favorably with those usually obtained with the ordinary Wassermann test.

3. Believing that digestive disturbances are important etiologically for imbecility and neuropathic states, the writer draws the conclusion that supervision and care of infants during the first year of life is an important prophylactic measure. He does not think that epilepsy can be prevented in this way. [G. C. S.]

2. Metchnikoff elaborates upon his former work, which claims that there is some relation between the alimentary poisons produced by bacteria and arteriosclerosis. The principal poisons are indol and phenol, and these are produced by the action of the bacteria which normally frequent the alimentary tract. This article reviews the results of experimental work with salts of indol and phenol on guinea pigs and rabbits. The guinea pigs did not show any lesions, but the rabbits did. He also cites human cases which in one way or another have been poisoned with carbolic acid and which show considerable signs of arterial degeneration. He takes up the question of diet and animals that live exclusively on one kind of food, and shows that animals representing each variety have sclerosis.

7. Wollman describes a rather clever device for testing loops of the intestine in regard to their bactericidal power. The small intestine juice and cells have, in his opinion, no bactericidal power in themselves. The absence of bacteria high up in the small intestine is due to the acidity of the gastric juice. [C. F., JR.]

Obituaries.

FREDERICK WILCOX CHAPIN, M.D.

DR. FREDERICK WILCOX CHAPIN, who died of angina pectoris at Springfield, Mass., on Dec. 15, 1910, was born on Nov. 7, 1849, in Middletown, Conn. He fitted for college at Phillips Academy, Exeter, N. H., and graduated from Harvard in 1870 with the degree of A.B. He studied medicine in New York at the College of Physicians and Surgeons, from which he received the degree of M.D. in 1873. After serving for two years as house physician at the Bellevue Hospital, in New York City, he settled in Springfield, where he continued the practice of medicine till the day of his death. He is survived by two daughters, by one son, also a physician, and by an infant grandson.

For more than thirty years Dr. Chapin was a member of the staff of the Springfield Hospital. He was an able surgeon as well as a skilled internist, but after a serious attack of pericarditis in 1898 felt himself obliged, to his keen regret, to relinquish surgery. He remained, however, a consulting physician to the hospital and became vice-president of its board of trustees. He was also a trustee of the Northampton Insane Hospital and a member of the Springfield Association for the Prevention of Tuberculosis, of the Springfield Academy of Medicine, and of the Springfield Medical Club. He was a fellow of The Massachusetts Medical Society, of which he was for many years councillor, and a member of the Hampden District Medical Society. He early became a medical examiner of the Massachusetts Mutual Life Insurance Company and in 1902 was appointed its medical director. Since 1898 he had also been a member of the board of United States examining surgeons for pensions.

Dr. Chapin was at all times an alert and progressive student of medicine and was prompt to adopt and make use of the many scientific discoveries and advances in method which revolutionized medical practise during his professional life. He won particular reputation for his early introduction into his community of tetanus antitoxin not only in the treatment of tetanus, but in its prophylaxis after blank-cartridge wounds. His rare professional ability, his integrity and his singular charm and beauty of character made him, for years, the most honored, trusted and beloved physician throughout the wide locality in which he was known. Though he was quiet and reserved in manner, his personality in the sick-room or the office brought comfort and confidence to all with whom he came in contact. To those whose privilege it was to enjoy his more intimate personal acquaintance he revealed himself as a man of delicate humor, of exquisite taste, sympathy and insight, and of loyal affection.

His friends hardly knew whether to admire and respect him more for the beauty of his domestic life or for the devotion and heroism that he gave to the practise of his profession, even under physical disability and personal sorrow and suffering. The manner of his death was what he or any true physician would wish for himself, for he discharged his daily duties to the end, and visited patients the evening before he died. His life exemplified the highest ideals of our profession, for it was one of unselfish and unremitting service. His memory will be cherished by all who knew him as an assurance of the enduring nobility of Christian virtue and a pattern of what is best and greatest in the character of the good physician.

JOHN C. DA COSTA, M.D.

Dr. John C. Da Costa,[1] who died of pneumonia in Philadelphia on Dec. 6, was born in 1834. He at first became a civil engineer and worked in that capacity nearly twenty years for the St. Paul & Duluth Railroad. Later in life he began the study of medicine and graduated from the Jefferson Medical College in 1878. He became instructor and afterwards demonstrator of obstetrics in that institution, and subsequently for over twenty years served as visiting gynecologist to the Jefferson Medical College Hospital. He was visiting physician to the Lying-in Charity Hospital, and visiting gynecologist to St. Agnes Hospital. He was a member of the American Medical Association, president of the Philadelphia Obstetrical Society, and a fellow of the College of Physicians of Philadelphia.

Miscellany.

MIDWINTER MEETING OF THE ÆSCULAPIAN CLUB.

The ninth annual midwinter meeting of the Æsculapian Club of Boston was held at Hotel Brunswick on Thursday evening, Dec. 15.

In addition to the members of the club, about forty invited guests, physicians of Boston, were present.

The speakers of the evening were introduced by the president, Dr. Robert M. Green.

Dr. John G. Blake, senior physician to the Boston City Hospital and a newly elected honorary member of the Æsculapian Club, spoke on "Medical Teaching Fifty Years Ago." He recalled many interesting and amusing features of the methods of teaching which prevailed at that time. Especially appreciated by the younger members present was his pleasant and vivid characterization of the personality of many distinguished teachers of an older generation with whom students of to-day have not had the opportunity and privilege of coming into contact.

The subject of the second speaker, Dr. George B. Shattuck, president of The Massachusetts Medical Society and also a newly elected honorary member of the Æsculapian Club, was "The Fugacious Years."

Reverting to the address made before the club two years ago by President Eliot, Dr. Shattuck commented on the unparalleled advances made in recent years by scientific medicine — progress which gives justification to the hope that the medical profession might, in time, attain its ideal goal, making itself unnecessary. He suggested, however, that though medical progress has been rapid, human progress, in the readiness of mankind at large to accept and follow completely the paths pointed out by science, has been distinctly slower and less satisfactory. The establishment of perfect correlation between human and scientific progress seems, therefore, likely to require years of patient and persistent effort. And in the lapse of future time there will be as great need as in the past for the daily human ministrations of the good physician.

The third speaker of the evening was the Rev. Samuel M. Crothers, of Cambridge, who took for his topic, "Literature and Medicine."

He remarked that the idea that when preventive medicine should be perfected the physician would become extinct reminded him of the similar problem which confronts the clergyman, that when all sinners are converted the church would no longer be needed.

Another point of similarity between the positions of the physician and the clergyman is the unique opportunity of each for discriminating reflection upon human life and human character. On the part of the physician, this discrimination, this diagnostic attitude, is the essence of his professional habit of mind and, therefore, fits him particularly for that criticism of life which finds its expression in literature. The best in literature is a by-product of other activities. That the press of these activities often prevents the doctor from making the most of the opportunities that might lead him into literature does not discredit the value of these opportunities.

Distinguished examples, like those of Sir Thomas Browne, of Rabelais, both a physician and a priest, and of Oliver Wendell Holmes, show that literary and medical pursuits are not incompatible, but mutually stimulating.

Whatever his aim in either field, the truest genius of the physician will manifest itself through that peculiar discriminating temper of mind which makes him, in creed, not a gnostic or an agnostic, but a diagnostic.

THE PREVENTION OF PLAGUE IN INDIA.

The report of the Punjab Plague Committee for the year 1910 contains twenty-six definite recommendations and conclusions. Some of the more important of these are as follows: (1) An active antiplague policy on the part of the government is necessary and should be continued. (2) The destruction of rats by means of poisoning and

[1] We regret exceedingly that, owing to an unfortunate misunderstanding, there appeared in last week's issue of the Journal an obituary notice under the name of Dr. John Chalmers Da Costa, who is, happily, still living. We apologize to him sincerely for this error, by which his name was confused with that of another member of the same distinguished medical family.

trapping on the present lines does not yield results commensurate with the expenditure incurred and should be discontinued; the greatest prospect of success in preventing the spread of plague by means of rat destruction consists in attacking the comparatively few localities where plague persists during the quiescent period. (3) Antiplague inoculation is essentially a personal prophylactic measure, and in recommending its adoption everything savoring of compulsion or pressure should be carefully avoided. (4) For dealing with plague epidemics in villages, evacuation is a most important antiplague measure. (5) The disinfection of infected houses during the course of an epidemic, or after its cessation, is not ordinarily necessary, but disinfection, as applied to the clothing and baggage of persons coming from infected areas, is a valuable means of preventing the spread of plague into uninfected areas and should be carried out wherever possible. (6) The only measures of a compulsory nature which are permissible are those demanded by public opinion and capable of being put into operation by the people themselves. Other recommendations deal with measures facilitating quarantine and isolation, and the extension of legal powers to the inhabitants of towns, as well as villages, to prevent the access of persons coming from infected areas, is advocated. — *British Medical Journal*.

Correspondence.

LETTER FROM PARIS.

A STRANGE SOURCE OF INFECTION. CONCERNING THE SURGEON ROUX. AN ABORTIVE TREATMENT OF SYPHILIS.

[*From Our Special Correspondent.*]

PARIS, Nov. 30, 1910.

Mr. Editor: The number of processes whereby the human body can get into serious trouble, or even be destroyed altogether, is so great that a feeling of astonishment frequently arises in the mind that any of us should be able to survive at all! There are certainly stranger methods than the one I recently heard of; but still, this one is so curious, and I imagine so little known, that the incident seems quite worth relating.

A few weeks ago a lady while walking in the forest of Saint-Germain, near Paris, scratched her hand in trying to get through some underwood. Nothing is commoner in the country than an accident of this nature, and as a usual thing of course these little wounds heal up without treatment or dressings. In this instance, however, the sequelæ of the accident were most alarming, to such an extent that the patient's life was for a while considered to be in danger; lymphangitis of the arm set in, with chills and pyrexia, the axilla became involved and had to be opened, and only after four weeks of incessant care and treatment was the patient's condition such that her medical advisers considered that they could report her to be on the way to recovery.

Now it appears that in the country cases similar to this are by no means pathological phenomena; such accidents occur every now and then among the peasantry, with sufficient frequency for the notion of the danger arising from wounds inflicted by *black* thorns to be a matter of current knowledge among them.

The curious side of the story lies in the genesis of these accidents, and nothing but a little knowledge of natural history can explain them, for the two reasons that immediately occur to the average mind,— that the wound became infected *subsequently*, or that the disorder may be of a nature similar to poison-ivy, — are neither of them founded on fact.

One of the common shrubs in this part of the world is the *berberis vulgaris*, or, as we would call it, the barberry, a plant that is provided with long and strong thorns. There is also a well-known bird of the lanius species in our woods known as the shrike in English. Now this bird, though scarcely larger than a thrush, is in reality a bird of prey, carnivorous, living off of insects, small birds and small quadripeds; it also has a habit of killing more than it wants or can eat for the time being, and in order that this excess of provender may not be wasted, but be available for emergencies, it creates for itself a larder by impaling its victims on the thorns of the *berberis*, where they hang somewhat like the carcasses of animals in a butcher's shop, and for this reason the shrike has also been called the butcher-bird.

The filiation of the accidents referred to above then becomes evident at a glance. The decomposing animal matter turns these particular thorns black, whence the peasant's dread of wounds inflicted by thorns of that color; and the nature and gravity of the lymphangitis occurring after such wounds is only too explicable, they being very similar, of course, to accidents occurring in the dissecting room. But at the same time these incidents would seem very mysterious without the help of a little natural history!

A man just returned from Lausanne brings some interesting details concerning Roux, the well-known surgeon of that locality, one of the very foremost if not *the* foremost surgeon of Europe. When I had listened to his account of the life that Roux leads, I felt that I must absolutely write to you about it, on the chance that it might come to the ears of our friend T. R., and possibly cheer him up in his present adversity, for this is a tale of a strenuous life if ever there was one; so far as I know there is only one other surgical center where anything similar goes on, — Rochester, Minn., — but there there are several operators, whereas Roux is alone.

Let us take first as a term of comparison the life of a professor of clinical surgery at the Faculty here, for Roux is professor of clinical surgery at Lausanne: About twice a week this professor turns up at an hour between 9 and 10 A.M., makes a rapid visit in the wards, adjourns to the theater, lectures on a case, operates on it, and disappears; on the other days of the week he may visit his wards, just as he may leave that to his *chef-de-clinique*. The official course of surgery will probably not begin until well into November; every chance is taken to get days off by profiting by the manifold holidays which the people has inherited from its Catholic days; and the course will end in June, after a duration of certainly not more than six months if honestly estimated. In a word, if the truth is said in this matter, the conduct of such a clinic approaches perilously near to organized shirking. Now let us see what Roux does.

Roux is a man between fifty and fifty-five, consequently by no means the young professor just appointed and anxious to show his zeal. He has the surgical service at the large cantonal hospital, and then his private clinic, where he can take upwards of sixty patients. At the hospital he holds a clinic for the students *every* morning of the week except Sunday from 8 to 9.30. He then operates, and this was the program on the morning my friend was there: Inguinal hernia; hysterectomy for myoma; two cases of appendicitis; tubercular synovitis of back of hand; excision knee-joint (tubercular); chronic osteomyelitis femur with removal of sequestra; amputation leg; resection two ribs, pleural fistula, gangrene lungs; two straightenings of flat foot under chloroform; cystostomy; dilatation esophagus,—thirteen interventions, ending at 1 P.M. On this particular day Roux was back at the clinic at 4.30, and stayed there until 9 in the evening.

The program of another day was as follows: Clinic to students, 8 to 9.30; seven operations at the hospital; twelve operations at his clinic; consultation at Neuchatel (a good hour away by train); two consultations at Lausanne.

Another day he was anxious to clear up what work there

was at the cantonal hospital in order to get away for a rest; so he began at 6.30 A.M. and operated on *twenty-five* patients!

Roux has two office consultations per week to which admission is only obtainable by application beforehand, and sees thirty patients at each of them, the cases being furnished with numbered tickets. He is now well on in his *fourth* thousand of interval operations for appendicitis.

Not the least remarkable side of this question is that Roux has come through all this success absolutely unspoiled, and that in particular his fees are so modest as to have become proverbial all over Europe.

Returning now once more to the "606"question, — the reports are certainly confusing, and it is difficult to know what to believe; even in Germany adverse criticism is not lacking, and quite recently a learned professor came out with a statement advising physicians not to use it outside of hospital work. All authorities seem agreed as to its marvelous efficacy in certain cases, but where they differ is in regard to its sequelæ, some saying that when properly used it is harmless, and others quite the opposite. The latest contribution to the question in France is the report just presented to the Academy of Medicine by Professor Gaucher, the successor of Fournier, in which "606" is handled rather roughly. In fact, although there seems to be no reason for anticipating that Ehrlich is in for such a disaster as happened to Koch with his tuberculin, there appears to be every prospect of our having to give up most of the hopes which the early reports concerning "606" had led us to conceive. We are already very far from the remedy that was going to sterilize the organism with a single injection.

However, at the same séance in which Gaucher's paper was read Hallopeau came forward with further details about what he calls his abortive treatment of syphilis; and since the cases dealt with in this manner have now reached a certain figure, and at the same time a respectable period has elapsed since they were so treated, it may be well to say a few words in regard to this method, as Hallopeau is a man of position here, elderly now, and was for many years one of the specialists attached to St. Louis Hospital for venereal and skin disorders. He has during the past year brought the matter before various learned societies, and in particular before the Academy of Medicine on four different occasions. It is, therefore, not possible to ignore what he says, and he states in so many words that he is now in a position to claim that syphilis can be aborted, and in a comparatively simple manner.

The point of departure of Hallopeau's method is that the disease remains almost entirely localized during its primary stage, and that it is possible to destroy the treponema in its initial localisations; he consequently attacks the disease *in situ* and administers parasiticidal injections every day for a month either beneath the skin of the penis or about the vulva, to speak only of the commonest seats of the disease, the needle being inserted either into the chancre itself, into the surrounding tissues or along the course of the lymphatics leading to the satellite lymph-nodes. Together with these injections he administers a general intensive treatment consisting in injections of 2 cgm. of hydrarg. benzoate, and from 1 to 2 gm. of KI. are given as well by the mouth.

The local specific used at first was atoxyl, helped out at times by arsacetine as a dressing for the chancre; but this was soon abandoned in favor of hectine, a synthetic product prepared by Mouneyrat and rejoicing in the chemical denomination of benzo-sulfono-paramino-phenyl-arsenate of soda. This was the only product that was tolerated by the delicate cellular tissue beneath the skin of the penis. The injections were at first painful, but this has now been remedied by neutralising this substance. Hectine is in reality atoxyl modified by the introduction of a radical sulfone. Arsacetine is likewise a derivative of atoxyl. Yet these products seem to have no deleterious effect on the patient's sight. It is true that the doses so far used have been moderate, 0.10 to 0.20, and that if this amount had not been freely exceeded with atoxyl we should probably not have heard of its action on sight. There is a farther preparation, hectargyrum, a combination of hectine 0.10 and of hydrarg. oxycyanide 0.002, that seems very promising and that Hallopeau proposes to experiment with at the earliest occasion.

His present technic is, then, to administer an injection of 0.20 of hectine each day for thirty consecutive days beneath the skin of the penis, dissolved in 2 gm. of sterilized water; he claims — and, in fact, when the question is considered the claim seems rational — that in this way the amount of active remedy that is likely to come into direct contact with the spirochetæ in or proceeding from the chancre is infinitely greater than when such a remedy is given in the hip, and *a fortiori* when given by the mouth. He thinks that it must be several thousand times greater, and that consequently the therapeutic result must be proportionately more favorable. Now since, according to his view, the disease in its first stage is confined almost entirely to the chancre, with the lymphatics leading to the nearest lymph-node barrier, the introduction of the active remedy directly into this tract seems as rational as that of the local treatment of a surgical wound with lymphangitis and lymph-nodes. Any spirochetæ that may have escaped the barrier and have got into the general circulation are dealt with by the general treatment mentioned above.

But now for results, for that is the test of the method. Hallopeau personally has treated by this method seventeen cases, his oldest case dating two years back and his most recent one seventy-five days, without a single instance of failure! The method has also been used once or twice preventively, but such negative cases of course prove nothing. With the seventeen cases several were substantiated by the ultramicroscope and by the Wassermann test. Now such a series as this in the hands of a man with Hallopeau's experience is one that commands attention. In one instance in which the abortive treatment was applied by another physician the patient was so much encouraged by the result that he managed to contract a second indurated chancre four months later, which looks as though either the treatment had been successful or else the diagnosis erroneous.

Hallopeau's experience, however, is as nothing compared with that of a specialist in Rio de Janeiro, who, having read Hallopeau's first publication on the subject, August, 1909, managed to treat 127 cases of indurated chancre therewith in the space of about six months, Rio being a town of 400,000. This practitioner claims that up to the date of his report not a single one of this enormous series of hard chancres had shown any sign of secondaries! If this should turn out to be true, and there is no reason at present for doubting the report, then there can be no question but that we are here in possession of (at the very least) an important modification of our ordinary treatment of the primary stage, and that, instead of our usual hip or back injections of biniodide we will be well advised to use the silver salts in small doses in injections *in situ*.

"S."

REPORT OF THE MASSACHUSETTS TUBERCULOSIS COMMISSION.

BOSTON, MASS., Dec. 13, 1910.

Mr. Editor: In the editorial upon the "Report of the Massachusetts Tuberculosis Commission" in your issue of Dec. 8, 1910, commenting on the recommendations of the commission "that the state pay a subsidy of five dollars per week for each non-paying patient in a local hospital which meets with the approval of the trustees of hospitals for consumptives provided tubercle bacilli are demonstrated," and that cities and towns with over ten thousand inhabitants be required to establish dispensaries for tuberculosis by agency of the local boards of health, you say: "Before they [these recommendations] become the basis of action, however, they should be subjected to rigid criticism, for in undertaking subsidy, the state is employing a dangerous agent. The taxpayer is already overburdened, and once the principle of subsidization becomes established and familiar, it is difficult to foresee to what extent it might be carried by those whose charitable enthusiasm is greater than their judgment or their own financial assets."

It may help your readers to conduct their "rigid criticism" to a sound conclusion and to understand the

economic advantages of the plan proposed if they study the plan of subsidy as it has already been applied in Denmark and Sweden.

Denmark is a poor country as compared with this and they have adopted this plan as an economic measure, as the cheapest way they can devise for bringing about an effective control of tuberculosis and stopping the enormous loss of lives and money which this disease occasions. The plan has the advantage of an equitable division of the burden of expense between the state and the various localities. It is a system under which the provision of beds is not likely to outrun the demand, each locality best knowing its own needs.

Your writer shrinks from the moderate cost of such a subsidy to the state and makes no allusion to the enormous loss to the state which tuberculosis causes. I would urge upon your readers a study of the careful article presented at the sixth International Congress by Prof. Irving Fisher, of Yale University, upon the cost of tuberculosis and its reduction. This is not the place to discuss this article at length, which should be read in its entirety to give an idea of the careful and fair way in which the figures are computed. Professor Fisher reaches the opinion that $8,000 is the minimum monetary cost of each death from tuberculosis, and subtracting from this $8,000 all that part of the loss which the consumptive himself may be regarded as having suffered, it leaves $3,200 as representing the economic loss to the community by the death of each consumptive. The deaths from pulmonary tuberculosis in the year 1909 were over 4,000 in the state. Accepting 4,000 as a round figure considerably below the truth, the economic loss was $13,000,000. The number of deaths from all forms of tuberculosis in that year were 5,998, showing an economic loss of $19,193,600.

This annual loss should be borne in mind when considering the payment of a subsidy of something over $300,000.

I would refer your readers to the report of the commission for a full consideration of the reasons which led them to think that segregation of advanced cases would reduce the death-rate and so would reduce this enormous money loss that the state is suffering each year.

In 1880, the death-rate in Massachusetts from tuberculosis was double what it is now. This means that the state is now saving $13,000,000 each year as a result of the improved conditions of living brought about by a better understanding of the laws of health, greatly aided by the work of the sanatoria and other health agencies.

Surely such a saving justifies the expenses of our health departments and sanatoria, without taking into account the relief of suffering and misery which has been an incidental advantage.

In conclusion, your writer says "that human progress is necessarily slow, that something must be left to natural processes, which can be aided, but not hastened."

This is an astonishing view to hold in reference to progress in medicine. He must indeed be an impatient person if the rate at which medical discovery and practice have proceeded in the past thirty years seems to him slow.

The fact appears to be that progress has been so rapid that the practical application of our knowledge is lagging somewhat. The suggestions contained in the report of the Commission on Tuberculosis point the ways by which an intelligent community may reap the benefits of the great advance in scientific medicine.

Respectfully yours,

ARTHUR T. CABOT, M.D.

APPOINTMENTS.

THE following appointments have been made at the Harvard Medical School: Dr. John Bapst Blake, Assistant Professor of Surgery. Dr. Robert Battey Greenough, Assistant Professor of Surgery. Dr. Edward R. Nichols, Assistant Professor of Surgical Pathology and of Surgery. Dr. Paul Thorndike, Assistant Professor of Genito-Urinary Surgery. Dr. Hugh Cabot, Instructor in Genito-Urinary Surgery.

SOCIETY NOTICES.

THE NORFOLK DISTRICT MEDICAL SOCIETY.—A regular meeting of the Society will be held at Masonic Temple, 171 Warren St., Roxbury, Tuesday, Dec. 27, at 8 o'clock. Business. Communications: "Some Common Diseases of the Lower Rectum and Anus." F. W. Sleeper, M.D.; "Rectal Fistulæ," T. Chittenden Hill, M.D. Discussion by E. W. Cushing, M.D., F. Percival Williams, M.D., Joseph C. Stedman, M.D. Refreshments after the meeting.

BRADFORD KENT, M.D., *Secretary*,
798 Blue Hill Ave., Dorchester.

BOSTON MEDICAL LIBRARY IN CONJUNCTION WITH THE SUFFOLK DISTRICT MEDICAL SOCIETY.—Medical Section Meeting, John Ware Hall, Wednesday, Jan. 4, 1911, at 8.15 P.M. 1. "Infectious Diarrhea, Its Clinical Treatment from the Bacterial Standpoint," Henry I. Bowditch, M.D.; 2. "Infectious Diarrhea, Its Bacteriology and Bio-Chemistry," Arthur I. Kendall, Ph.D.; 3. "Analysis of 175 Cases of Infectious Diarrhea in Infancy," Jas. Herbert Young, M.D.—all from the wards of the Boston Floating Hospital. Discussion by Drs. T. M. Rotch, J. L. Morse and F. B. Talbot.

EDWIN A. LOCKE, M.D., 311 Beacon St.
HENRY JACKSON, M.D., *Chairman*, 380 Marlborough St.

RECENT DEATHS.

HARPER, ALFRED ALPHONSO, M.D., M.M.S.S., died in North Adams, Nov. 14, 1910, aged thirty-four years.

CHAPIN, FREDERICK WILSON, M.D., M.M.S.S., died in Springfield, Dec. 17, 1910, aged sixty-one years.

DR. ROBERT HALL, who died of apoplexy last week at Providence, R. I., was born in 1829. He graduated from the College of Physicians and Surgeons, New York, in 1856, and subsequently studied medicine in Vienna. He was a homeopathic practitioner, but made a specialty of gynecology.

DR. CARL H. KROEBER, a well-known physician of Yonkers, N. Y., died on Dec. 12, at the age of forty-one years. He was a native of Germany, and was graduated from the College of Physicians and Surgeons, New York, in 1896. He had served as vice-president of the J. Foster Jenkins Medical Society of Westchester County, and at the time of his death was visiting physician to St. Joseph's Hospital, Yonkers.

PRINCIPLES UNDERLYING THE STUDY AND TREATMENT OF CHRONIC ARTHRITIS.

BY H. W. MARSHALL, M.D., BOSTON.

THE term "chronic arthritis" brings to mind confused classifications, obscure etiologies and unsatisfactory treatments which justly make it unpopular with practitioners, but joint affections are not rare and patients demand treatment notwithstanding the unattractiveness of their troubles. Definite and, as far as possible, scientific conceptions of chronic arthritis are, therefore, particularly needed concerning the rationale of causes and cures.

With these needs in view the writer has devoted himself almost exclusively for several years to the study of arthritic patients and examination of the writings of past generations of physicians who have struggled with the problem. As a result he believes that he has gained a little better understanding of the subject and one which may perhaps be of interest to those who, while they are confronted with its difficulties and obscurities, have had less time or opportunity for its careful consideration. The present paper deals mainly with the fundamental principles involved, and extended discussions of special methods, examples of actual cases and results of treatment are reserved for future communications.

In his work the author has had the great advantage of the frequent advice and counsel of many physicians and other friends, to all of whom he desires to express his obligations and thanks, and in the preparation of this paper especially to Dr. Theobald Smith, Dr. Wm. H. Howell and Prof. W. T. Sedgwick.

Patients may be grouped for convenience into the following clinical classes. (1) Incipient Cases; (2) Moderately Severe Cases without Joint Destruction; (3) Acute Exacerbations of Chronic Disease; (4) Very Severe Cases with Joint Destruction and Disability.

Well-known and fundamental principles naturally governing the treatment of all of these classes are so easily forgotten or neglected that a brief summary of them at the outset may be useful, for proper treatment can only be secured by thorough comprehension of those normal anatomical and physiological features which control the health and ordinary activity of joints and by clear appreciation of the various diseases that may be accompanied or followed by arthritic phenomena. The Etiology of Chronic Arthritis has already been discussed by the author in a previous paper, to which the reader is referred.[1]

NORMAL PHYSIOLOGICAL CONDITIONS WHICH CONTROL THE HEALTH AND ORDINARY ACTIVITY OF JOINTS.

All healthy joints are constantly being subjected to normal physical, chemical and nervous stimuli through mechanical movements, strains due to body weight, external physical agencies, physical and chemical conditions of the blood, and also to nervous impulses transmitted to and from joints and articular blood vessels through trophic and sensory nerves; and all pathological conditions must arise from departures from these normal relations. Moreover, joints cannot be influenced by any other means than by those just enumerated. The health of all organs and tissues depends upon normal physiological processes going on within tissue cells by which living material is built up from food substances of the blood, energy set free, and waste products eliminated. It varies in degree according to variable combinations of these physical, chemical and nervous stimuli, and it depends also upon the inherent properties of the protoplasms themselves, as protoplasms vary greatly in different tissues and with different individuals.

Individuals may be considered to be "robust" or "delicate" according as the sum total of their various tissue resistances is respectively great or small. Moreover, the interaction of different tissues, each upon the other, which doubtless influences this sum total of cellular tissue resistance and eventually determines to a large extent the general health of the individual, sometimes affords an opportunity for the study of individual organs by observing the effect of the conditions of other organs upon the one selected for study. With joints it is possible to estimate to some extent the various degrees of arthritic resistance and normal activity by observing the pathological conditions in organs that are contributing deleterious substances to the blood stream and thus are affecting articular structures, either directly through chemical and physical stimulation of joint tissues, or indirectly through chemical and physical stimulation of nerve cells in the cord which, in turn, react by transmitting unusual and perhaps undesirable stimuli to joints and articular blood vessels.

We are met at the outset by a significant fact, namely, that with diseases of other organs arthritic phenomena are comparatively infrequent, a fact which must be interpreted to mean that joint resistance is generally sufficient to withstand those abnormal blood states to which joints are frequently exposed. The small percentage of cases of this kind which do display arthritic phenomena must apparently either represent joint tissues of poor resistance or exceptionally abnormal conditions of blood and lymph, or else abnormal conditions in controlling nerve cells. It is a familiar fact that severe infections often occur without any arthritic phenomena, while at other times even mild infections of the same kind may have associated with them severe joint complications. It seems reasonable, therefore, to conclude that, while the joints, as a rule, are peculiarly healthy and resistant, they may occasionally be weakened or non-resistant even to an extreme degree.

As will appear later, this idea of variable resistances in the cell protoplasms of various tissues or organs, including, of course, the joints, coupled

[1] Etiology of Chronic Arthritis, Johns Hopkins Hosp. Bull., July, 1910.

with the idea of variability in stimuli from without, is of fundamental importance in scientific diagnosis as well as in prognosis and rational treatment. Again, it must not be forgotten that the former, cell resistances, are particularly obscure and are dependent upon the stimuli from without and upon congenital peculiarities of the protoplasm.

DISEASES ACCOMPANYING OR ASSOCIATED WITH JOINT LESIONS.

Diseases which occasionally may influence the health and behavior of joints comprise a long list that includes nervous, infectious and constitutional affections, the more important of which will now be mentioned, because they must not be forgotten or overlooked when seeking for the causes involved in any given case.

Acute articular rheumatism, gout, rheumatoid arthritis, osteo-arthritis, influenza, scarlet fever, typhoid fever, bacillary dysentery, amebic dysentery, malaria, pneumonia, septicemia, tuberculosis, gonorrhea, syphilis, tonsillitis, oral and nasal sepsis, otorrhea, pulmonary abscess, gastro-intestinal disturbances, diseases of thyroid gland, spleen, lymph nodes, infections of the gall bladder, kidneys, male and female genito-urinary tracts, hemophilia, scurvy, anemias, lead poisoning, syringomyelia, tabes dorsalis, paralysis agitans, congenital heart disease, puberty, pregnancy, menopause, erysipelas, furunculosis, psoriasis, osteomyelitis and chronic suppurative conditions. (See Arthritis Deformans, R. Lewellyn Jones; and Bulletin of the Committee for the Study of Special Diseases, T. S. P. Strangeways, for statistics of relative frequency of associated diseases.)

Sometimes only one focus of infection contributes its products to the blood stream, but sometimes several foci may exist. At times one cause may initiate the arthritis and other causes perpetuate it. Sequence in time of development of several questionable factors, therefore, should be considered, as the oldest lesions may be primary causes and others be merely accompaniments that are cured with removal of the primary trouble; but these secondary accompaniments contribute their pathological products to the blood also and may thus exert an influence upon the joints. Gastro-intestinal toxemias resulting from the inactive life of patients often seem to be grafted on to the original process, and perhaps sometimes perpetuate it.

As might be expected, common diseases appear more likely to be common causes of joint disease than rare disturbances of internal organs which some investigators would invoke to explain obscurities associated with arthritis. According to the writer's experience, while the latter may indeed be very rarely contributing factors, the commonest causes are apparently bacterial infections, digestive disturbances, abnormalities in metabolism associated with puberty, pregnancy and the menopause, and unstable conditions in nerve cells controlling the joints.

METHODS OF TREATMENT OF CHRONIC ARTHRITIS.

Methods of treatment consist in application of appropriate remedies, and in attempts to restore physiological relations in joints; to repair defects due to strains, traumata and excessive mechanical irritation; to overcome abnormalities of the blood and do away with harmful exposure to climatic influences; to rectify, as far as possible, derangements of the nervous control and to thus increase health and resistance of the joint tissues.

Some remedial measures act locally, others are employed in treatment of diseases of organs when these stand in causal relationship with joint disease; and there are also general hygienic measures to be applied.

Local treatments are applied to lessen excessive mechanical irritation, increase or diminish blood supply, alleviate pain, prevent and correct deformities, restore mobility and remove pathological tissue, hypertrophied villi, joint mice, loose cartilages, etc. These objects are attained by orthopedic apparatus, plaster casts, splints, bandages and strappings; by hot and cold applications, bakings, Bier's passive hyperemia, massage exercises, electricity and operations of various kinds.

Diseases of other organs standing in causal relationship to joint diseases can exert their influence directly upon joints only through the blood, and indirectly through the action of blood upon nerve cells with production of unusual nervous stimuli, as already explained. Blood presumably owes any irritating qualities to the presence of particular toxins, to undue accumulations or deficiencies of normal products of metabolism of tissue cells, and probably also to its mere physical properties. Nervous stimuli depend upon the state of the blood and upon inherent peculiarities of nervous tissues, just as joint conditions depend upon these states of the blood and inherent peculiarities of joint tissues; and when nerve cells are robust and healthy the nervous element in joint disease is at a minimum; when they are weak or diseased, the nervous factor becomes of greatest importance. Irritants circulating in the blood stream are most obscure in their nature and are called toxins, metabolic products and internal secretions, but comparatively little is known of the chemical constitution or molecular grouping by which they exert their influence upon joint structures. Bacterial toxins, which are among the best recognized of these complex organic bodies, can be identified only by their therapeutic effect upon animals, although it is possible to cultivate them outside the body *in vitro*. The precise chemical nature of metabolic products of organ activities are quite as poorly understood. In gout it is known that sodium mono-urate circulating in the blood is somehow concerned with the pathological process, but physiologists are still discussing whether gout represents defective diminished elimination by the kidneys, excessive production by the body tissues or faulty processes in liver associated with conversion of purin bodies of the food, or whether various factors are combined. Variability in vital resistance of joint tissues has

to be considered in gout as in other types of arthritis, but the exact chemical reaction upon joint tissues of the soluble urates in the blood is not well understood.[2]

In lead poisoning the metallic element gets into the circulation presumably as some organic combination of the proteid molecule and exerts its selective action especially upon nervous tissues whereby arthritic pains are occasionally an accompaniment of this disease, but here again the exact chemical substance which reacts upon nervous tissues is unknown.

Products of bacterial activity in the intestinal tract are absorbed into the blood and in cases of acute ptomaine poisoning make their influence very evident; also there is absorption of products from bacteria habitually present in the intestinal tract which may accumulate in the blood from over-production, or possibly through diminished elimination by the kidneys, and these are capable, apparently, of producing joint changes much as excess of uric acid derivatives in the blood may produce arthritis when patients have susceptible joints; but the exact chemical nature of these bacterial products has not been determined.

Relations between joint diseases and lesions of uterus, thyroid gland, spleen, lymph nodes, lungs, heart, kidneys and formed elements of the blood itself undoubtedly exist, yet it is not well understood whether such joint lesions are induced by bacterial infections, disturbances in metabolism of tissue cells, reflex nervous derangements or combinations of these; for blood conditions always are obscure, and although it may contain irritants, yet routine blood examinations offer little aid in explaining the existing states.

Control of the properties of blood which are so vital to health of joints, therefore, must be made by search for, and treatment of, different organic diseases and infections; and while it is not possible to enter into details of treatment for all derangements of organs, fevers and foci of infection, yet it is necessary to understand and remember their existence in order to accurately interpret and treat any given case.

General hygienic methods of treatment increase metabolic functions of tissues generally and help to restore depleted conditions such as are frequently observed at the onset of arthritis. Through the action of these general measures the blood becomes altered and contains different proportions of food substances and metabolic products from all tissues, while foci of infection, if they exist, are more successfully resisted, as the protective functions of the tissues against foreign substances are stimulated and blood flowing through joints exerts healthier action. Nervous stimuli presumably also are changed by this altered blood condition and joints are able to perform their physiological functions more perfectly and consequently slowly begin to improve.

General hygienic methods consist in the regulation of personal habits, administration of medicinal tonics and physical therapeutic measures.

[2] A. Magnus-Levy: Uric Acid in Gout. Am. Jour. Med. Sci., vol. cxl, November, 1910, pp. 625–643.

Personal habits should be carefully investigated, occupations inquired into and changed when necessary; diet, sleep, rest and exercise regulated; and mental disturbances and drug habits ascertained.

Medicinal tonics comprise such drugs as strychnine, quinine, iron, arsenic, iodides, phosphates and others which exert their influence more or less upon the protoplasms of all tissues and help to repair defects that each is subject to.

Physical therapeutic measures consist in application of heat, light, mechanical and electrical stimuli in various forms of baths and massage for the sake of their tonic effects. For the various forms of special treatment reference must be made to the voluminous literature upon the subject, as they include sun and air baths; artificial radiant heat baths; hot, neutral and cold water baths, and these are often combined with mechanical friction or electricity and chemical substances in most confusing combinations. The importance of general hygienic measures in treatment of arthritis is here especially referred to as these measures will be frequently mentioned in what follows.

The writer uses for routine treatments at hospital clinics the pharmacopeial preparations, tincture of nux vomica, and elixir of iron, quinine and strychnine phosphates for general tonics, and calomel, magnesium sulphate, sodium phosphate, fluid extract of cascara sagrada, and rectal lavage with warm water at frequent regular intervals to clear the intestinal tract and regulate digestive functions. Usually treatment begins by purging with calomel and magnesium sulphate, and this is followed for several weeks with daily rectal irrigations. Finally the irrigations are given less frequently, and fluid extract of cascara sagrada and sodium phosphate are prescribed to assist evacuation upon days on which irrigations are not used.

Diets have to be regulated in order to prevent reaccumulation of foods in the digestive tract and to avoid continuance in formation and absorption of bacterial irritants from the intestine that injure joint tissues. Diets also must be so regulated as to supply sufficiently large amounts of food materials to maintain the health of other body tissues and to keep up the individual's general resistance and vigor. Accurate rational directions for diet regulation in arthritic disease the writer is unable to give at present, but reliance can be placed upon simple modifications in quality and amount of food until the right diet is experimentally discovered. This important subject of diets in arthritic diseases the writer now has under consideration, and which it is hoped may furnish the basis of a future paper.

Strong hydrotherapeutic measures should not be prescribed for arthritis because this class of patients do not respond well to the more vigorous methods, and the writer is informed by Dr. J. H. Kellogg that he uses only mild ones at Battle Creek Sanitarium, where he has found from his extensive experience that arthritic

patients will not bear strong, continuous stimulations. Sun baths and changes in climatic environment seem especially adapted to arthritic and rheumatic states. Mild irritants that have acted for long periods of time in producing joint lesions should, therefore, be combatted by mild remedies for long periods in order to restore normal functions, and more stimulating measures should be reserved for occasional use to upset recurring lapses into chronic pathological states.

When occupations and circumstances have produced very unhygienic modes of living, simple regulations of personal habits sometimes are sufficient to start patients towards recovery. Inquiry into personal habits is too often overlooked, and not infrequently failures of treatment may be traced to neglect in ascertaining and rectifying simple yet most important errors in habits. Sanatoria and health resorts scattered throughout the country furnish interesting and convincing evidence of the frequent efficacy of simple hygienic measures in cure of diseases. These establishments prosper because they cure patients by correcting defective habits while patients are kept entertained and occupied with a routine which constitutes each particular "cure." These methods are often scornfully regarded on account of their simplicity, yet it is just as well to admit their importance as very many persons are benefited, and the fact that some patients are made worse and that recurrences occur after these simple measures are stopped should not lead us to overlook the fact that many improvements undoubtedly do take place. Instead of underestimating the efficiency of simple methods, it is safer to consider that regulations insisted upon at sanatoria if permanently adopted would very often result in permanent improvements.

INCIPIENT CASES OF ARTHRITIS

Patients frequently seek medical advice for slight pains and stiffness in various joints, and for swellings which make their appearance upon the fingers, in order to learn whether severe arthritis is likely to develop, and what should be done to arrest its progress. It is often impossible to say whether or not there will be serious trouble later, but the best estimate generally depends upon application of such ideas and physiological principles as have been explained, and although diagnosis and prognosis is often impossible at the outset, yet our methods of treatment are sufficiently definite and may result in cure in spite of our ignorance of precise underlying causes.

It is the writer's custom with incipient cases to obtain accurate ideas of patients' past diseases, their inherited and acquired tendencies, occupations and habits of life; and from a complete but rather superficial physical examination to locate gross abnormalities in organs and active infective foci; also to observe at the time the state of the general health as well as mental and nervous conditions. When active pathological processes are discovered, these are immediately treated, but when only indefinite, mildly suspicious conditions are found, as is often the case with this class, then reliance is placed upon general hygienic methods to correct all irregularities, and if cures do not result, further treatment is then instituted as explained under the next section upon moderately severe types of arthritis.

General hygienic measures have been described, and those applicable to incipient cases consist in administrating tonic medicines, as nux vomica, combinations of iron, quinine and strychnia; or iron, arsenic and strychnia; and in correction of personal habits. The latter are not too greatly restricted in these mild cases, but diets are simply modified when they are obviously defective and the digestive tract is emptied and kept cleared by means already described. It should be remembered that digestive disturbances are numbered among the commonest of maladies and are starting points for deviations from the normal processes concerned with elaboration of food materials for the tissues and that, therefore, treatment of digestive abnormalities is a very important means of changing the quality of the blood and of influencing all organs. Gross errors in habits of sleeping and taking exercise are also rectified. Local treatments are of less importance and when needed consist in mild stimulation with radiant heat, high-frequency electrical applications and warm dry protective coverings for the affected joints. Salicylates are also indicated in small doses at times when pain interferes with sleep.

Patients who do not improve are then treated as outlined under moderately severe types of arthritis, but the dividing line between these two types is an arbitrary one and transitional stages occur. This classification is simply convenient for descriptive purposes.

Summary. — Diagnosis in incipient arthritis depends mainly upon personal histories of patients and superficial general examinations; prognosis is very often impossible to determine at the outset; treatment is directed towards undoubted pathological conditions when these exist, and otherwise consists in general hygienic measures.

MODERATELY SEVERE TYPES.

These are most typically represented by chronic, well-developed polyarticular joint diseases in which joint destruction is slight and changes have not gone on that require manipulations or local operations. Monarticular types of moderate severity, however, have also to be considered in this class.

Preferably these patients should be kept in a hospital under observation for a few weeks until all suspicious circumstances revealed by histories and the unusual states found in examinations have been carefully considered, and until interpretation of these data is accomplished and an idea is gained of the relative importance of mechanical and nervous factors, of external influences and influences acting through the blood, after which subsequent treatments may be outlined as seems best.

Questions often arise with regard to what shall be done with patients who have only suspicious conditions in various organs but no well-defined, active lesions. Shall all these suspicious foci be radically treated like well-defined ones on the assumption that they really are the causes, although obscure, and that the arthritic process is likely to continue until they are removed? Concerning this question observation shows that there are occasional patients with obstinate arthritis who have been subjected in turn to many radical operative treatments without relief. Treatment to them has meant unnecessary discomfort and a series of expensive experiences in addition to their arthritic disease; moreover, such examples seem difficult to avoid when patients are plucky and willing to try all remedies, and their arthritis is obstinate, because there is such diversity of opinion among the medical profession regarding causes and treatments. Better understanding of joint diseases is needed, therefore, to avoid injury from attempted treatment of incurable cases as well as to restore health in those who do respond to treatment.

It is well in our present stage of enlightenment to recognize that some patients cannot be cured, although theoretically they should be, because it is a fact that some are not relieved and failures seem due in part to lack of recognition of underlying causes when the disease is in its early stages and can be most advantageously attacked.

Methods of treatment in moderately severe cases of chronic arthritis. — Patients are put to bed and kept out of doors as much as possible; diets are reduced to meet the requirements of the inactive life, and modified as tests indicate. Stomach and intestines are cleared of food accumulations to prevent possible bacterial toxemias; and general medicinal tonics and drugs for relief of pain are used sparingly, the latter only to insure sleep and comfort. Passive movements must be given daily or patients allowed to arise from bed a few hours each day if joints show tendencies toward stiffening, and gentle massage may be used to supplement passive movements. Pathological processes in other organs, if unquestionably active, are treated immediately.

Within a few weeks a considerable proportion of cases will show distinct improvement; others will show very little change; and the remainder will grow worse. Those showing improvement should continue to receive the same treatment, and if suspicious foci have been located in other organs, these should be observed until doubts are dispelled or confirmed. Sometimes these foci disappear under hygienic treatment and at other times they become more definite and localized, requiring attention before complete cure is effected. Cases which show no improvement in the first few weeks should, nevertheless, have their treatment continued unchanged, as general hygienic measures act slowly, while the advantage of removing merely questionable foci cannot be told until the focus is removed, and experience demonstrates that such operations frequently have little effect upon the joints. When the disease does not begin to improve within a few months, or grows steadily worse, decisions have to be made which depend upon the particular circumstances presented by each individual case. The safety, comforts and dangers of neglect of conservative methods; the risks, discomforts, benefits and disappointing results of operative procedures; the rate at which arthritic disease is progressing; the confidence and mental attitude of the patient; the degree of definiteness of suspicious lesions, have all to be considered.

At this stage before radical treatments are instituted upon uncertain grounds attention is urgently directed once more to the nervous control of joints, as it is the writer's belief that many cases are primarily of neuropathic origin, and at the risk of repetition reasons for this opinion will be given.

It should be remembered that the nervous system controls every important organ and co-ordinates all activities as is shown by the general health of the individual; and the influence of nervous control of joints may readily be observed in the very destructive joint changes following spinal cord lesions, as in syringomyelia and tabes dorsalis.

In the more severe cases of rheumatoid arthritis (atrophic arthritis) there have also occasionally been found appreciable pathological changes in spinal cord and meninges when they have happened to be examined.

The physiological relationships between nervous tissues, joint tissues and body tissues may be recalled to make clearer the ideas which follow:

Nerve cells continually influence body tissues (including joints), directly through trophic and vasomotor nerves, and also, by modifying metabolic activities of different tissues in varying degrees, indirectly influence all tissues through interactions among the latter. Conditions of the blood stream are changed and proportions of metabolic products from each tissue vary as the result of nervous stimulation and activity.

Nerve cells are continually affected by sensory nervous impulses, by the metabolic products of organ activities and food products, and occasionally by the metabolic products of bacterial activity in the blood when infective foci are present.

Joint tissues and all body tissues, as explained, may be influenced through trophic nerves, metabolic products of organ activities, food products and occasionally bacterial products in the blood.

Nerve cells, joint tissue cells and all body tissue cells exhibit variable degrees of vitality, all may be robust or delicate, and many theoretical combinations are possible. For example, lung tissues may be delicate and other tissues vigorous in one individual; kidneys alone be defective in another; liver and gastro-intestinal tract exhibit abnormalities in a third; and *delicate joint and nerve tissues* be the most pronounced defects of a fourth. The latter theoreti-

cal possibility is the one to which attention will be directed, and evidences for its existence sought in pathological changes which can be anatomically demonstrated as well as suggested by functional abnormalities that may be clinically observed.

Evidence to be readily accepted must rest upon a visible or recognized basis; biological principles and physiological laws are more likely to be stigmatized as too theoretical; but so many conditions depend upon invisible physical and chemical processes going on within tissue cells that it is unwise to ignore these biological and physiological principles as they constitute the only adequate means of interpreting invisible metabolic disturbances of cell activities. Neuroses belong especially to this class of disturbance having no visible anatomical basis, and lesions in rheumatoid arthritis seem to be just at the transition line between visible and invisible processes, as some of the severest cases exhibit visible changes in spinal cord substance, peripheral nerves and diffuse patches of spinal meningitis while mild cases do not show any visible lesions.

(Reference should be made to the chapter on morbid anatomy of rheumatoid arthritis in R. Lewellyn Jones' book, "Arthritis Deformans," for an admirable presentation of anatomical changes observed in that disease.)

Gross pathological evidence will be disregarded in this article and attention directed to those functional disturbances in various organs which may possibly signify abnormal metabolic processes taking place in their controlling nerve cells. In rheumatoid arthritis (atrophic arthritis) muscular atrophy often occurs so rapidly and to such extreme degree that it cannot be satisfactorily explained by atrophy from disuse; moreover, special muscle groups are usually affected; cutaneous pathological changes include pigmentation, sweating and, in later stages, dryness and harshness, with desquamation and thinning of the skin; local circulatory disturbances are seen in the waxy white fingers and cyanotic appearance of the extremities. Sensory disturbances are observed in premonitory sensations of tingling and numbness, stinging and burning feelings, soreness, streams of pins and needles and muscular cramps. Tendon reflexes are increased. Visceral disturbances are represented rarely by gastric crises, and frequently by light or severe abnormalities in digestive functions.

The following case typically illustrates many of these points.

Single woman, thirty-seven years of age. Arthritis developed at three years of age; five severe acute attacks up to eighteen years of age with complete restoration in function after the first ones. Continuance of attacks of greater severity involving all joints with permanent impairment in joint function until patient became confined to wheel chair or bed. This disabled condition she has now been in for several years. She was a delicate child and had scarlatina, measles, pleurisy, influenza, carbuncles and tonsillitis, also a nervous collapse which lasted two years; and further injured her health from study when at college. She is a small, slightly built woman with lively tendon reflexes and wonderfully good mental development, and her readiness to try new remedies has resulted in operations upon tonsils, nose, mastoid, joints and gall bladder, besides various physical therapeutic treatments. No very definite infective foci have been discovered by any of the competent physicians who have treated her, and she has progressively grown worse. Remedies which have temporarily arrested the disease have been a quiet life out of doors with attention to simple hygienic measures, and these restored her health from a bedridden state to one in which she could walk again, although with difficulty. Continued overexertions brought on another acute attack from which recovery was very slow until she was again sent to a quiet country place and kept out of doors with only sufficient entertainment to insure contentment; and again the joint pains lessened, muscular spasm relaxed and joint motion appreciably improved.

With each attack there has been excruciating pain, fever, extremely rapid muscle atrophy, cutaneous disturbances and periods of indigestion, and each recovery has been characterized by restoration of muscles, return of normal digestion and subsidence of muscle spasm, articular pains and cutaneous disturbances. When the patient had an acute mastoid infection of great severity, there was marked diminution in arthritic pains and increased mobility of the joints which persisted for a month or so afterward. The bacterial toxins of the mastoid infection did not increase joint symptoms, as might be imagined they would do if articular structures were susceptible to bacterial poisons. Their toxins, however, produced fever and accelerated tissue metabolism, so that the blood temporarily was changed and presumably acted in different manner upon all tissues, *including joints and nerve cells controlling the affected joints.*

Similarly there has been noticed in this patient very abrupt cessation of articular pains and increased mobility of joints following ether anesthesia. The effect was very striking and transformed excruciatingly painful joints immediately into much more comfortable ones as soon as recovery was made from the anesthetic. Relief from symptoms in this instance lasted nearly two weeks before pains and spasm slowly returned. Ether anesthesia is known to increase metabolism of the tissues, also exerts profound influence upon nerve cells, and while nothing can be proved by these observations, yet the unusual response of nervous tissues may indicate pathological processes in them.

Another point in favor of nervous instability in this patient is shown by gastric disturbances noticed when arthritic pains are worst; and these visceral manifestations have caused so much discomfort that cholecystotomy was performed, but only an inflammatory state was discovered. Bacteriological examination of stools and chemical examination of the urine have shown exceptional freedom from intestinal putrefactions. Relief afforded by salicylates, tonic hydrotherapeutic baths and electrical treatment harmonizes with the idea that the nervous element is a very important one in this instance, and absence of any definite focus of infection after prolonged search and failures of radical treatments strongly help to confirm it, as does also the long course of arthritic disease beginning in early childhood.

These data probably will not seem convincing as they are read for the first time, but deliberation and attempts at other explanations of these clinical facts strengthen the plausibility of the neuropathic theory,

which has very many adherents among those who are best informed.

The writer wishes to point out that many elements enter into the etiology of each case of arthritis and that nervous influences are constantly at work, sometimes in a normal, unobtrusive manner and sometimes in obvious pathological ways; and that when the degree of nervous derangement is great, arthritis may properly be considered of neuropathic origin.

Summary. — It is always impossible to understand exactly the complex relations that exist between body tissues, the endless series of influences that are exerted to and fro continually between every organ upon every other one, by means of nervous stimuli and shifting states of the blood. Such interactions, however, obviously do exist, and it seems reasonable to suppose that when nerve centers which control joint structures directly or when nerve centers which control other organs indirectly influence joints through the blood, if these nerve centers are seriously defective, then prognosis for joints is poor, irrespective of the question whether such nerve cells are congenitally weak or have acquired defects from injuries sustained in severe infectious fevers, because normal metabolic function of nerve cells can be restored with difficulty when they are once seriously injured.

Estimation of the nervous factor in the etiology of any given case of arthritis can be made only imperfectly by the personal history and suggestive physiological manifestations in various organs, and the practical effect upon treatment is simply to delay radical measures still further and to encourage continuance of general hygienic treatments which are often efficient means of restoring the health of nerve tissues as well as of all other tissues. But if improvement does not occur, operations will probably be resorted to sooner or later whether they are beneficial or not, on account of the doubts and differences of opinion which must necessarily arise.

Vaccine treatment should be given a trial while conducting hygienic treatments and before operative procedures are instituted, because injection of bacterial cultures after the living organisms have been artificially destroyed has frequently been tried upon infectious arthritis with some temporary improvement of arthritic conditions.

Such bacterial products undoubtedly cause a general reaction in the tissues and there are temporary improvements corresponding to temporary altered states of the blood whereby local infections are more successfully resisted for the time, but joint conditions which have come on and become chronic from long residence in the tissues of resistant bacteria are much less favorably influenced by inoculations of bacterial products than acute infections which have already been successfully resisted and localized by the individual. In the latter conditions injection of bacterial products is frequently followed by rapid clearing up of infective foci, and the inoculation reaction appreciably accelerates the mastery over the parasitic micro-organisms.

In the writer's limited experience there have not been very many permanent benefits observed that can be definitely attributed to vaccine treatment, but investigators who have had more experience are confident that considerable benefit is derived not infrequently, and it is conceivable that bacteria in the tissues in chronic as well as acute states occasionally exhibit sufficiently low degree of resistance to enable the general tissue reaction from inoculations to just turn the balance in favor of the individual and to overcome the parasitic bacteria.

Operations upon other organs include removal of tonsils and teeth; operations upon nasal bones and sinuses; curettage and drainage of osteomyelitic foci in many localities, curettage of uterus; salpingectomies, hysterectomies, colostomies, cholecystotomies and operations for suppurative conditions in various organs. Special indications cannot be given, as each depends upon the special circumstances which exist in each individual case, and some of them, as, for example, hysterectomies, have not been done for arthritis alone, but because local disease of the uterus demanded its removal, yet in these cases severe arthritic disease which existed simultaneously has been permanently cured.

Local treatment in moderately severe types which show no serious joint destruction consists of protective or stimulating measures. Normal muscle balance tends to be destroyed by atrophies, also by spasms in various muscle groups, and joint contractures consequently tend to occur and may be treated by local stimulation of affected muscles, massage and electricity. Normal position may be retained with aid of orthopedic apparatus and plaster casts. Synovial membrane hypertrophies due to excessive mechanical irritation require measures to restrict and minimize motion, by bandages, adhesive strappings and plaster casts.

Local measures include bakings, hot and cold applications, dry and moist applications, chemical counter-irritants, massage, passive motions, Bier's passive hyperemia, various forms of electricity and radiant heat; and all are rather indiscriminately used to combat pain and swelling. Some cases are benefited temporarily and others are not influenced, but prediction cannot be made what the effect will be in many instances until trial is made. High-frequency electrical treatment relieves arthritic pain often in atrophic arthritis and gout. The physiological action of local measures usually is a double one through direct stimulation of joint tissue cells and by modifications of blood and lymph supply to the parts. When there is reason to suppose the blood is at fault, caution should be exercised not to wear out the tissues that are already struggling with unfavorable conditions by over-stimulating them with therapeutic agents. Protective methods used for various joints will not be described in detail, — the strappings and supports for feet; strappings, bandages, casts, iron braces for knees, hips and spinal column; plaster jackets, corsets, collars, shoulder braces, cuffs, gloves and other appliances used by orthopedic surgeons.

From what has already been said concerning normal physiological factors that control health of joints it will be evident that local measures are of secondary importance and palliative in cases

not produced by mechanical and external agencies, but nevertheless are useful. Mild treatments should be tried first and their results closely watched, as mild irritants have acted for long periods of time to produce the pathological conditions, and restoration can be brought about best through similar mild prolonged treatments.

ACUTE EXACERBATIONS OF CHRONIC ARTHRITIS.

These are treated by the same principles that are used in chronic processes, but require modifications on account of their severity. Acute exacerbations of chronic rheumatoid arthritis (atrophic arthritis), acute onsets of arthritis due to bacterial infections, acute gouty attacks and acute rheumatic fever are confused because they are often much alike in their arthritic manifestations and require similar local treatments. Underlying immediate causes of acute attacks are obscure, perhaps being due to sudden entrance into blood stream of irritating substances in unusual amounts or of unusual toxicity; or perhaps are caused by the sudden breaking down of cell resistances in joint or nerve tissues. These suppositions are supported by recognized facts. Showers of uric acid in the urine accompany acute exacerbations of gout; rapid development of bacterial infections are followed by abrupt onset of arthritic symptoms as soon as joint resistances are overcome. Joint and nerve tissues react variably according to the severity of stimuli which are acting upon them and according to the resistance of their cell protoplasm; and premonitory symptoms and abrupt onsets of arthritis so often observed can be easily understood upon this biological basis. When irritants in the blood are of moderate severity and joint cell resistances are of moderate degree, slight premonitory symptoms occur and subside as the tissues react successfully at first before they finally break down in their normal function, but when weak tissues are overwhelmed with irritants of greatest toxicity, they succumb with surprising abruptness. Abrupt onsets of nervous symptoms, as, for example, delirium and mania, probably are manifestations of similar overwhelming conditions that suddenly destroy the physiological balance in nerve cells, and nerve cells which control joints and articular blood vessels show pathological conditions suddenly arising in them by suddenly producing arthritic lesions. The actual case cited in this article is an example which the writer believes to have an important neuropathic element and exhibits at times sudden onsets of arthritis with extreme symptoms of prostration, fever, sweats and involvements of all joints in an exquisitely painful process.

Underlying causes of acute cases must be sought by methods which have already been described, and methods for local treatments also remain unchanged, but are applied with greater vigor. Inflamed joints are kept perfectly quiet by means of splints or plaster casts, thus entirely removing mechanical irritation; gouty attacks in which subsidence can soon be expected may properly be treated by active local stimulation of the joint tissues with electricity to temporarily increase cell resistance and metabolism, and some gouty patients find they are thus able to avert milder attacks if such electrical treatment is taken immediately when first symptoms become evident. With other patients such active local stimulation seems inadvisable when the blood is likely to contain irritants for a considerable time, and stimulation then may aggravate instead of ameliorate local joint conditions.

Variations in external physical influences should be prevented by dry protective coverings applied to the affected joints. Increasing the blood supply sometimes means increasing the amount of toxic influence, while decreasing the blood supply means diminution in necessary food products of the blood and perhaps an inadequate removal of waste products. The best circumstances in each instance can only be determined experimentally, and in practice thermal measures of heat and cold may be tried cautiously, and if improvement occurs they are persisted with, but abandoned if no relief is afforded.

Drugs are almost always given to control pain and are justifiable on account of the important influence pain has upon the resistance and total metabolism of the individual.

VERY SEVERE TYPES OF ARTHRITIS.

These fall into three groups; those in which mild irritants have acted for a long period and caused slow disintegration of joint structures; those in which severe bacterial irritants cause more rapid destruction of the joints, and those due to mechanical and traumatic causes. Conditions seen in gout, certain cases of rheumatoid arthritis (atrophic arthritis) and osteo-arthritis (hypertrophic arthritis) represent the first group, and bacterial infections with organisms themselves growing in joint tissues are examples of the second class.

Treatment of the first class consists principally in correction of deformities and in restoration of joint motion. Attitudes habitually assumed during acute stages of the disease often result in permanent deformities, as, for example, the forward bending of the cervical spine due to propping the head up with pillows, and the stooping attitude of such patients from fixation of the vertebræ by bony overgrowths when in improper positions in bed. Faulty attitudes lead to faulty physiological functions, and bony overgrowths in joints of the extremities often require operative measures to remove obstructing bony tissue and to restore motion. Osteotomy of the femur is a familiar operation in treatment of ankylosis of hip with deformed position, and this procedure helps to restore the normal attitude and muscle balance, thus preventing secondary deformities, and consequently assists in maintenance of the individual's normal physiological functions.

The second class, tuberculous, gonorrheal, pyogenic and other infections of the joints, require aspirations, arthrotomies for washing out joint cavities and for removing necrotic material. Various injections have been employed; for

example, oils to prevent post-operative adhesions and oxygen to inhibit growth of anerobic micro-organisms. Frequently arthrotomies are performed for other reasons, to remove hypertrophied synovial membranes and loose cartilages, but none of these methods will be discussed and are simply mentioned to complete the outline of clinical classes proposed at the beginning of the paper.

RÉSUMÉ.

An attempt has now been made to describe as exactly as possible how joints may be influenced by normal physiological factors; mechanical, nervous and external stimuli; and by physical and chemical properties of the blood; and to enumerate the different diseases that may alter normal nervous control of joints and normal states of the blood.

Physiological pictures of metabolic activities going on in all living tissues, and the ways by which different ones react upon each other, have been described, because normal states of the blood and of nervous tissues depend upon normal functions and reactions of every individual organ.

Attention has been called to the fact that vital processes going on within tissue cells cannot be accurately measured at present by chemical or physical means, and in early stages of many diseases intracellular pathological processes leave no visible anatomical evidence of their abnormal action, notably in nerve cells which produce abundant physiological evidence of deranged function but only meager visible proofs of it, so that physiological effects produced upon other organs furnish the only adequate means of recognizing and estimating the intensity of these invisible, intracellular pathological processes that act through nerves and blood.

All manifestations of arthritic disease, including joint defects, lesions of other organs and all clinical symptoms can be more readily understood upon this physiological basis as representing departures from normal conditions that exist in healthy states.

Description of methods of examination and special methods of treatment have purposely been avoided as much as possible, and confusing nomenclatures have also been kept in the background in order to make clearer the importance of these principles; yet it should be recognized that adequate examinations and skill in application of special methods contribute as much as general conceptions to success in treatment. The latter, however, are so easily forgotten or neglected, and their neglect is responsibile for so many failures, that they are here emphasized. Application of these principles will establish their value in determining why some patients are curable and others are non-curable.

Permanent cures of arthritis depend upon permanently removing the causes which are producing the disease, and this is possible, first, when infective foci are present which may be completely removed by surgical means; secondly, when arthritis is produced by acute infectious fevers which subside and no longer exert their influence; thirdly, when defective metabolic processes in tissue cells can be permanently altered into healthy activity, and, finally, when defective personal habits and unhygienic occupations are recognized and may be regulated.

Infective foci may be permanently removed when they occur in tonsils and teeth, and when chronic suppurative conditions elsewhere can be radically treated or removed. Obstinate cases of fecal impaction may cause severe arthritis, and permanent cures are possible when such unsuspected intestinal conditions exist that may readily be prevented from recurring. Operations upon the gastro-intestinal tract which restore normal relations in it and prevent bacterial toxemias theoretically also may permanently cure arthritis.

Defective metabolic processes in tissue cells that are independent of bacterial action often are difficult to permanently restore to a normal state, and success in treatment here depends at present mainly upon early applications of simple hygienic measures before metabolic abnormalities have become too extensive or too chronic.

Regulation of defective personal habits and unhygienic occupations are the simplest, also one of the most important and most efficient, means of increasing the number of cures of all types of arthritis.

Incurable cases of arthritis are represented by bacterial infections of vital organs that cannot be operated upon and which are resistant to general hygienic measures. Examples are also seen in nervous maladies in which there are serious defects of nerve cells that cannot be reached; and as already mentioned, also in patients whose unhygienic occupations and faulty habits must be continued for financial reasons. Some patients are born with such non-resistant joints that they are almost certain to become impaired in spite of treatment, by repeated attacks of arthritis in acute fevers and infections, and these patients also are likely to become incurable.

Paul Ehrlich's apparently successful treatment of syphilis by means of an arsenical chemical compound which destroys the spirochetes of that disease in the tissues without injuring the tissue cells of the host arouses the hope that he may be able to prepare other chemical substances in the same purposeful manner that he has done with syphilis, that will be specific for other parasitic cells, common pyogenic micro-organisms and others. Such specific chemical substances would be of inestimable value in combatting bacterial diseases of inoperable vital organs, and would appreciably lessen the numbers of incurable arthritic patients. Theoretically, such chemical substances exerting their toxic effect directly upon foreign parasitic cells in the tissues seem much more likely to be efficacious than injections of bacterial toxins that produce a general protective reaction of the body tissues and indirectly exert greater inhibiting influence upon local foci of infection through temporary changed conditions of the blood.

Conception of arthritic disease as being either self-limited or incurable is erroneous and unjustifiable upon theoretical grounds and also is unsupported by actual evidence furnished by patients who have been permanently cured. All degrees of acuteness and chronicity of arthritis can be observed, and anatomical changes range from perfectly normal to completely disintegrated pathological states.

Statistics of cures may always be questioned when many influences are acting, but prompt restoration of normal health and function of diseased joints occurs so frequently as soon as rational treatments are instituted that no reasonable doubts exist of their important influence, although absolutely incontrovertible proof seems likely to be an impossibility for an indefinite time to come.

The writer's experience with arthritic patients for several years, therefore, has led him to the following inferences:

(1) The causes of chronic arthritis are many, and arthritis must be considered a symptom of many diseases rather than an entity that is produced always by the same specific cause.

(2) Causes generally are common diseases of other organs, common infections and ordinary defects of personal hygiene rather than obscure and rare diseases.

(3) The most severe deforming types of arthritis that stubbornly resist treatment and the mildest kinds that are easily controlled and permanently cured have similar origins. They differ only in the degree of severity with which the underlying causes act.

(4) Arthritic disease in every stage may often be modified by treatment, sometimes only slightly, and sometimes to a great degree, permitting permanent cures not infrequently.

(5) The best period to initiate treatment is in the incipient and early stages before chronicity is established, although the later stages also must be attended to when the disease has progressed to that degree.

(6) Diagnosis and treatment of incipient and early arthritis depend upon thorough knowledge of physiological conditions that control health and normal activity of joints, and cures result when defects in these conditions can be recognized and remedied.

(7) Proper application of simple hygienic measures and correction of defective personal habits are the most adequate means of treatment in the early stages.

(8) Increased efficiency in treatment depends upon greater clearness in understanding of normal physiological conditions that control health of joints, and also upon increased skill in treating diseases of other organs and infections that act as causes; and such knowledge of physiology and increased skill in treatment should be strongly advocated as well as search for new methods and new causes, for obscure conditions generally may be explained more satisfactorily as confusing combinations of common causes than by assumption of unknown rare pathological processes.

(9) New methods for treatment of chronic arthritis are likely to consist of very dissimilar ones, special drugs, organ extracts, vaccines and physical therapy applied to diseases of different organs and to infections; and better comprehension of physiological conditions governing the health of all organs may also be advantageously emphasized.

(10) Future advances in treatment of arthritis, as in pulmonary tuberculosis, appendicitis and some other diseases, probably will be towards prevention of extensive pathological changes by early recognition of the disease, and treatments will tend to become comparatively simple ones that prove themselves to be efficacious in these incipient stages.

RADIUM THERAPY.*

BY LOUIS WICKHAM, M.D.,

Chief of the Department of Surgical Pathology of the Radium Institute of Paris.

CHARACTERISTICS OF RADIUM.

RADIUM emits three kinds of rays, the so-called alpha, beta and gamma. The alpha and part of the beta (the soft) forms have but slight penetrative power, while certain of the beta and all of the gamma are capable of exerting influence deep within the tissues. In therapeutic work the alpha and the soft beta rays are employed where superficial results are wanted, as in diseases of epidermis and upper corium, or again where caustic action is needed, but as a rule other modes of destruction can be employed which are cheaper and more rapid in their effects. It is the deeply penetrative action of the hard beta rays and of the gamma rays as a whole which gives radium its most practical value.

The power of penetration of these rays is indeed extremely great, but the depth at which these rays act therapeutically depends not only on this penetrative power alone, but also on the number of the rays which attack a given point and on the susceptibility of the given tissue.

This really great penetrative power is illustrated by a recent experiment in which a cancer of the breast 15½ cm. in width was treated for forty-eight consecutive hours with the enormous dose of 19 cgm. of pure radium sulphate spread on shields 28 cm. square. During this exposure an electroscope and a screen of platino-cyanide of barium were held on the opposite side of the breast, and both instruments showed the influence of radium emanations, the former in eight to nine seconds.

Before this exposure the breast was a hard, bosselated, homogeneous mass, but sixteen days later it had shrunken 1 cm. in width, and palpation revealed a series of nodules. The breast was then amputated, and on section one could see that the portion of the tumor lying directly in the path of the rays differed totally from the remoter zones.

* The salient points of a lecture delivered at the Boston Medical Library at the request of the Surgical Section of the Suffolk District Medical Society. This paper is compiled by Dr. Charles J. White, from data left in his hands by Dr. Wickham.

The former area was divided into several smooth, hard, white, scirrhous nodules, while the latter regions were irregular, pink and encephaloid.

Macroscopically we have just described the results of radiation. Microscopically we shall now see how the rays affected the structure of the epithelial and the stroma cells.

Action on the epithelial cells. — This action is destructive, and this destruction is produced by a form of cellular degeneration appearing exclusively in the neoplastic elements, an elective necrosis so to speak, one affecting the whole cell, body, nucleus and nucleolus. The cell becomes enormous and its acidophile protoplasm is condensed into a peripheral membrane. In this mass one sees often pseudo-parasitic or fuchsinophile bodies. The huge nucleus, filling at times almost the whole cell, is irregular, budding, pale or highly colored, and the nucleoli are also greatly hypertrophied. The chromatine appears either in its usual clear, well-defined, filamentous form, or becomes diffuse, the nucleus coloring homogeneously. Or again the chromatine is scattered through the cellular protoplasm, suggesting rupture of the nuclear membrane (karyorrhexis); or the nucleus disappears entirely, leaving visible only its membrane (karolysis).

Action on the stroma. — This action shows itself around the islands of pathological epithelial cells by the presence of young connective tissue very rich in cellular elements which penetrate and break up the tumor mass. This tissue will bring about the cicatrization following the necrosis and disappearance of the cancer cells. This infiltrate of vasculo-connective buds is composed principally of young fibroblasts and lymphocytes, surrounding the newly formed capillaries. There are also at times masses of plasma cells, and again one finds at rare intervals cells to which one attributes the function of phagocytosis, i. e., polynuclear leucocytes, neutrophiles, large mononuclears and giant cells.

Disappearance of neoplastic elements and subsequent cicatrization — this is the apparent action of radium.

Looking more closely into the details of the penetrating power of radium we find at a depth of 1 to 6 cm. a region of connective tissue, a region where scar tissue is in the making or is complete — the zone of cicatrization. At a depth of 6 to 9 cm. we note degeneration, not complete, but well under way — the zone of degeneration. Below this comparatively great depth there is evidence of change and pathological unrest, but these disturbances are too delicate to describe.

A very interesting and valuable characteristic of radium is its selective action, a quality inherent in x-rays also. Both of these forms of energy act primarily on the more highly organized animal tissues, and it is the epithelial structures first which feel the influence of both of these rays. Not only is this true, but it can be demonstrated that the most actively growing epithelial cells are influenced even before their more normal brothers. Thus radium can modify cancerous cells and arrest their malignant evolution without producing any changes in the surrounding or adjacent epidermic cells. We base this assertion on positive microscopic facts.

Referring once more to these sections of skin subjected to the enormous dose of 19 cgm. of radium we find that sebaceous and sweat glands lying between the skin and the underlying cancer were hardly affected, while the deeper cancer cells were actually destroyed. This power of selection is all the more striking in this instance when these cells were lying directly in the path of the most intense action of the radium.

Another quality of radium or, more properly speaking, an absence of quality, is its strictly local action. With x-rays observers have noted that after radiation of a given plaque of psoriasis, or of eczema, other affected regions at any distance will clear up. This quality is unhappily not present in radium. Exposure to radium means the amelioration of that particular area treated. This is strictly true, at least in cancer, for neighboring glands remain as before, and metastases are wholly unaffected.

METHODS OF APPLICATION.

Radium may be applied in the form of tubes when it is intended for cavities, and is spread on cloth, inserted in a glass capsule of any given shape and then surrounded by a given envelope of lead, aluminum or other metal, depending upon the degree of filtration deemed proper.

When not intended for deep sites, radium may be applied on metallic or cloth bases.

The metal base is usually of copper sufficiently thick to be rigid and bearing a roughened face to which the radium varnish may adhere. The form of this base may vary in size and shape, depending upon the region of the body to be treated. These bases should vary in size from 1 to 30 cm. square. Concave bases are useful in the case of eyelids, cheek bones, etc., convex when treating the naso-malar or naso-palpebral regions. When intended for cavities, canals, folds, fistulas, etc., the metal base is usually cylindrical, and, of course, varies in diameter and length. Laminated bases are a useful form to insert behind eyelids, into the nasal cavity, etc.

The cloth bases need no elaborate description. They are simply constructed of cloth of varying size and shape, and are especially useful when large surfaces are to be treated with comparatively weak preparations, the forearm with chronic eczema, for example.

On these metallic or cloth bases we spread a varnish, permeable, solid and resistant, in which we incorporate our radium.

SCREENS.

In the beginning we stated that the three varieties of radiations possessed different penetrating power. To produce deep reactions we depend for the most part on the gamma rays; but one method of preventing the superficial caustic action of the alpha and of the beta rays is essential, and this is safeguarding of the surface, accomplished by the interposition of certain sub-

stances which check the alpha and beta rays. There is a tendency, nowadays, however, to employ certain of the beta as well as the gamma rays in therapeutic work. For this purpose one can employ absorbent cotton, rubber, tin, mica, gold, silver, copper, lead or aluminum, but of all of these substances, lead and aluminum are perhaps the best.

Aluminum possesses many advantages as it can be rolled out into sheets as thin as $\frac{1}{100}$ mm., but the most practical thicknesses vary between this extreme and $\frac{5}{100}$ mm. The malleability of lead, on the other hand, is limited for practical uses to $\frac{1}{10}$ mm., and although it has the great superiority of pliability, still its weight, its uncleanliness and its lesser permeability render it less valuable than aluminum for filtration purposes.

Thus far we have considered the application of radium to surfaces of the body or to recesses and canals already existing anatomically, but a still greater scope is given to radium therapy by calling to our aid surgical measures. First, we can ask the surgeon to introduce our applications into more inaccessible parts, the esophagus, the rectum, the bladder, etc., or again we may ask him to make deep incisions in tumors, or to open the thoracic or abdominal walls; and by such procedures the applicability of radium becomes universal. By such surgical interference we have been able to treat large tumor masses of the surface, cancer of the pylorus (gastric fistula), of the uterus, bladder, rectum, larynx, etc.

Many therapeutists have been content to treat their cases from one point of attack only, but an enormous advantage accrues by allowing rays to penetrate simultaneously from several directions, and from the whole surface, and even from the interior as well, if it is thought advisable. This is our method of "cross-fire," a method which materially reduces the time of exposure and greatly enhances the value and enormously increases the scope of radium therapy.

DISEASES AMENABLE TO RADIUM THERAPY.

Carcinoma.

First in importance from a therapeutic point of view come the various types of carcinoma.

It is well understood that superficial epitheliomata yield in 95% to the action of radium, but from our point of view the surgeon can accomplish this same result in a much shorter space of time by simple excision. There are, however, certain sites on which cancer may grow and from which an excision may produce poor cosmetic results. Such unfavorable seats are represented by the nostrils, the mucous membrane of the nose or mouth, the conjunctivæ, the eyelids and the ears, and here we are much inclined to favor the use of radium, which will cure in these foci as often as the knife, and in accomplishing the parallel result not demand disfiguring and permanent loss of tissue.

If, however, the patient is one who has an ingrained aversion to the knife or to anesthetics, we may rely upon radium to remove vegetating, ulcerating or nodular cutaneous cancers in the great majority of cases. Or if there has been a previous operation and one or more subsequent recurrences, the patient may prefer to try something else besides surgical interference.

In malignant cancer of the rest of the body we must regard radium merely as an adjunct to the surgeon. Operation and excision should always come first, if possible, and a radiologist who ignores this viewpoint renders himself culpable in the eyes of the best modern medical thought. Per contra, the surgeon who is ignorant of, or blind to, the possible therapeutic aid of radium treatment, errs equally toward his patient. Experience shows that radium, applied by the most modern methods, is capable before an operation of delimiting the new growth and revealing more clearly to the surgeon his field of operation. Manifold experience has demonstrated that radium is often capable of holding in check further rapid extension or recurrence even of cancers previously operated upon once or oftener. Experience again has taught us that radium may prove of inestimable value in alleviating pain, and in drying up and deodorizing the foul, ulcerating, inoperable or recurrent cancers of the uterus, bladder, rectum or other parts of the body.

Leucoplakia.

Leucoplakia, recalcitrant to all forms of treatment, may yield to the influence of radium.

Hypertrophied Scars.

Cheloids following sinapisms, burns, operations or ulcers in certain peculiar individuals have usually proved a stumbling block to medical or surgical treatment. The disease known as dermatitis papillaris capillitii (acne keloid) and the disfiguring fibrous bands following scrofuloderma of the neck have likewise been a source of worry to the medical world. Radium seems to have an especially favorable action on these hitherto distressing, often painful and always obstinate affections.

This amenability of cheloidal tissues to radium is due to the fact that the rays can exercise on them a special action which causes them to disappear by simple absorption and by gradual regression without exhibiting the least revulsion or clinically visible inflammation. In order to produce this selective action it is sufficient to use doses which are not strong enough to create surface irritation.

Angiomata.

Vascular naevi, considered from the radium therapeutic point of view, may be divided provisionally into four groups:

A. Flat angiomata, superficial and level with the skin.

B. Flat angiomata, level with the skin but deeply invading the cutaneous and subcutaneous tissue and mucous membranes.

C. More or less raised angiomata with smooth or papillated surface.

D. Soft and pulsating angiomata in fluctuat-

ing areas, and erectile angiomatous tumors situated under the skin or on the mucous membrane.

We all know what a puzzle these varieties of vascular tumors have been in the past from a therapeutic point of view. Electrolysis, caustics, x-rays, knife and CO_2 snow have been our chief weapons in the past, but radium offers us to-day a means, and perhaps the best means, of ridding the patient of these disfiguring birthmarks.

The "cross-fire" method of application finds its most accurate and useful employment in the treatment of angiomata. By combining it with weak or medium filtering it considerably increases the intensity of the most deeply penetrating (*surpénétrant*) rays, whilst allowing some action to those of medium penetration.

Pigmentary Naevi.

The pigmented moles and birthmarks offer rather an unfavorable target for radium. There is no specific influence exerted in this tissue, that is, there is no selective action, and to accomplish results one must produce inflammatory reactions. But even by this method, which we have learned is fortunately unnecessary in vascular new growths, we may accomplish often striking results. On the other hand, it is best not to treat by radium, hairless, slightly *café au lait*, superficial patches. The resulting chalk-white scars and the frequently resulting telangiectases produce a disfigurement greater than the original lesion.

Hairy Naevi.

Radium has a distinct action on the pilo-sebaceous glands, and depilation is not a difficult process by this means. The cosmetic result is good, and we have not to fear the ugly and numerous small scars which follow the destruction of hairs by the x-rays.

Tuberculosis Cutis.

The various forms of tuberculosis of the skin may be treated by radium, but the rays have no selective action on tuberculous tissues, and to accomplish results one must employ the emanations as a destructive agent. This treatment requires powerful action, both wide and deep, and long-continued and careful supervision of the resulting scars. Tuberculosis of the mucous membranes can, however, be improved without any perceptible reaction. As to the permanent value of the results in the treatment of tuberculosis, they are inferior in every way to those obtained in carcinoma, angioma and keloid.

Miscellaneous Diseases.

In the course of our work we have been led to try the therapeutic power of radium on various recalcitrant diseases, and it is interesting to record varying favorable results in obstinate cases of psoriasis, angiokeratoma, linear ichthyosis, several forms of dyskeratosis and hyperkeratosis, lichen planus, acne rosacea, rhinophyma and certain types of papilloma. We do not wish to consider radium as the first therapeutic choice in all these various diseases, but simply ask you to bear in mind that, when other and more accessible means have failed to produce cure or alleviation, that as a last resort radium may accomplish the desired curative results.

ANALGESIC EFFECTS OF RADIUM.

There can be no doubt of the power of radium to relieve congestion, and this ability and the alterative qualities of the emanations have proved of great service in relieving the pains of certain epitheliomata and carcinomata and of numerous keloids. We are able to record also relief in many cases of neuralgia, including that accompanying and that following herpes zoster, neuritis, gonorrheal and rheumatic arthropathies and iritis, and other experimenters have gained frequent favorable results in the deeper-seated pains of gastritis, tabes dorsalis and sciatica.

Such favorable experiences led us to try the effects of radium in the pruritic diseases of the skin, and as a result we have met with decided success in the relief of pruritus ani, with and without accompanying hemorrhoids, pruritus vulvæ, neuro-dermatitis, lichenification and chronic eczema. We have accomplished these results by the use of rays of weak and medium penetration which seem to have a selective action on pruritus and produce their favorable results without concomitant inflammatory reaction.

Our method of procedure in the treatment of such necessarily large surfaces, as occur in chronic eczema of the arm, for instance, is to apply the radium in the form of a varnish spread on linen. Our technic in combating these disturbances of nervous origin is to employ large apparatus with powerful radio-activity; to make short exposures with intervals between them; to use weak and medium rays in as large numbers as possible; and to avoid superadded inflammation.

[*Note.* — A large part of the evening was devoted to the exhibition of lantern slides illustrating graphically the truth of Dr. Wickham's spoken words, and the audience seemed much impressed by the modesty and sincerity of the speaker. — C. J. White.]

THE CARE AND MANAGEMENT OF THE TABETIC BLADDER. II. ETIOLOGY.

BY J. DELLINGER BARNEY, M.D., BOSTON, MASS.,

Assistant Surgeon to the Genito-Urinary Out-Patient Department, Massachusetts General Hospital.

(From the Genito-Urinary Out-Patient Department, Massachusetts General Hospital.)

In a previous paper (Boston Medical and Surgical Journal, Dec. 22, 1910) the writer discussed the signs and symptoms of tabes dorsalis. I will now attempt to explain their causation.

At the outset I would say that this is a matter of some difficulty. This is owing to the fact that not only is the anatomy of the urinary mechanism, especially the sphincter apparatus, still in more or less dispute, but the nervous control of the bladder functions is even more a matter of controversy. Such a state of affairs exists in spite

of innumerable researches, both clinical and experimental.

The muscular structure of the bladder proper is clearly described. It consists of three coats of unstriated muscle: an outer, whose fibers are chiefly longitudinal in direction; a middle, the direction of whose fibers is mainly circular or transverse; and an inner, arranged more or less longitudinally like the outer coat, but with many of the muscle bundles obliquely disposed. The latter is usually incomplete, being found only on the inferior wall, and to some extent on the superior wall. It is not found on the base of the bladder. No sharp line of demarcation exists between the different layers. This is especially true at the neck of the bladder, where all the coats are more or less intermingled. The so-called "detrusor urinæ" is generally considered to consist of the longitudinal fibers, with or without the circular fibers. Thus, broadly speaking, when we say "detrusor," we refer to the bladder muscles as a whole.

Many writers deny the existence of a true internal sphincter of the bladder. Without going into a discussion of the merits of the arguments, I will say at once that, according to the best of evidence, such a sphincter does exist. Further, all are agreed on the presence of an external striated sphincter. The bladder outlet is, therefore, guarded by two sphincters, an inner of smooth muscle, and an outer of striated muscle. The latter is often referred to as the urethral sphincter, or by the familiar names of "cut-off muscle" or "constrictor urethræ," as it divides the membranous from the bulbous urethra.

For an account of these sphincters I shall draw freely from the recent description given by Albarran and Noguès. The smooth muscle fibers of the anterior urethra, scattered throughout its length, join in forming a more or less complete ring at the peno-scrotal angle. This, however, plays no part in urination. These fibers extend upwards in two layers, an inner longitudinal and an outer circular, to surround the membranous and prostatic urethræ (Fig. 1, 9 and 10). At the neck of the bladder there is the internal sphincter of smooth muscle, formed by a continuation of the fibers already described into those of the inner (Fig. 1, 14) and middle coats (Fig. 1, 15) of the detrusor muscle. It is the middle (circular) layer of the latter, thickened at the bladder neck, and continuous with the outer circular coat of smooth muscle fibers surrounding the urethra, which is called the internal or smooth sphincter (Fig. 1, 8). It is the tonicity of this sphincter which prevents involuntary evacuation of urine.

Around the membranous urethra there is found a powerful external sphincter of striated muscle, which prolongs itself upwards like a horseshoe with the opening posterior, along the whole anterior aspect of the prostatic urethra, external to the prostrate itself, up to the bladder (Fig. 1, 7; Fig. 2, *A*, *B*, *C*, *D*, 3). When the prostatic urethra and the neck of the bladder are removed, as in total perineal prostatectomy, incontinence does not occur. This is due solely to the presence of the striated sphincter surrounding the membranous urethra.

In the female, the anatomy of the external sphincter is identical with that of the male, except for the interposition of the prostate in the latter. Owing to this, and to the presence of the vagina, the striated external sphincter of the female completely surrounds the urethra at the bladder neck, while below it is open behind. Its relation to the urethra is thus reversed in the female.

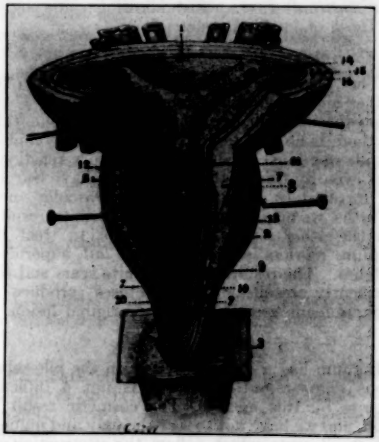

FIG. 1.—Longitudinal section showing, 1,1', Bladder and trigone. 2, 13, Prostate. 3, Triangular ligament (inferior layer). 4, Neck of bladder. 5, Verumontanum. 6, 6', Prostatic and membranous urethræ. 7, External striated sphincter. 8, Internal smooth sphincter. 9, Longitudinal smooth fibers of urethra. 10, Circular smooth fibers of urethra. 11, Urethral mucosa. 12, Vascular coat. 14, Internal muscle coat of bladder. 15, Middle muscle coat of bladder. 16, Outer muscle coat of bladder.

The accompanying illustrations, photographed from those in Testut's "Traité d'Anatomie Humaine," show the anatomy of this region very well. Fig. 1, with its explanatory legend, will make clear the appearance of the two sphincters in longitudinal section. It also shows the relation of these sphincters to the three layers of the detrusor muscle. For the appearances of the two sphincters in cross-section the reader is referred to Fig. 2 and its appended description.

It was stated above that the tonicity of the internal sphincter alone prevented involuntary micturition. As evidence of this, Albarran and Noguès recall the fact that when the prostatic urethra is divided, incontinence does not occur, although striated muscle is not found in this location. The tonicity of this sphincter has also been amply demonstrated by the experiments of Courtade and Guyon. They found that even without any nervous excitation the

internal sphincter will resist a pressure of 12 or 15 cm., occasionally 20 cm., of water.

On the other hand, the resistance of the external sphincter has been shown by these investigators to equal a pressure of from 70 to 100 cm. or more of water. It is thus seen that the presence of two distinct sphincters has been well demonstrated on both anatomical and physiological grounds, and it has also been shown that each sphincter offers its own special resistance to pressure.

In considering the nerve supply of the bladder and sphincters, we find ourselves at once in a bewildering maze of theory and fact. According to Courtade and Guyon, the nerves of the bladder, including the internal sphincter, come from the hypogastric plexus, situated in the loose connective tissue on both sides of the middle part of the rectum. This plexus receives its fibers from two sources, — from the sacral nerves (usually the third and fourth), and from the inferior mesenteric ganglion. The branches from the sacral nerves running to the plexus are two or three in number and are known as the nervi erigentes. They run straight to the plexus without passing through the sympathetic chain. There is also evidence (Guyon, Albarran and Testut) that in the course of these nerves, and even in the detrusor muscle itself, there are numerous ganglia. Their presence is not as yet fully demonstrated, and their action is far from clear. The external sphincter is supplied not only by branches from the hypogastric plexus, but also by a branch from the internal pudic nerve.

The vesical spinal center is said to be on a level with the third and fourth sacral segments of the spinal cord (Frankl-Hochwart), although it is fair to say that its precise location is still in doubt. Another center is found in the medulla. Also, according to Frankl-Hochwart, there is evidence to show that in the brain there is a center in the motor area of the cortex, and a subcortical center in the striate body, and probably also in the optic thalamus. Impulses for urination are believed to travel along the lateral pyramidal tracts.

To quote Albarran and Noguès, "All organic functions are the result of a reflex, and micturition offers no exception to the rule. In every reflex three things are necessary, — sensory nerves, a center and a motor nerve. The sensory nerves transmit the excitation to the center, which transmits it in its turn to the motor nerve."

As regards the action of these nerves and the particular part supposed to be supplied by each, I will give briefly the results of the experiments of Guyon. The latter, working with Courtade in 1895, showed conclusively that the sacral nerves act only on the longitudinal fibers of the bladder, while the hypogastric nerves act only on the circular fibers. As the longitudinal fibers are the ones chiefly concerned in the evacuation of the bladder, they concluded that the act of urination depended almost exclusively on the nerves coming from the medulla by the intervention of the sacral plexus. Further experiment in 1900 led Guyon to conclude that the nervi erigentes were at the same time the sensory and motor nerves of micturition.

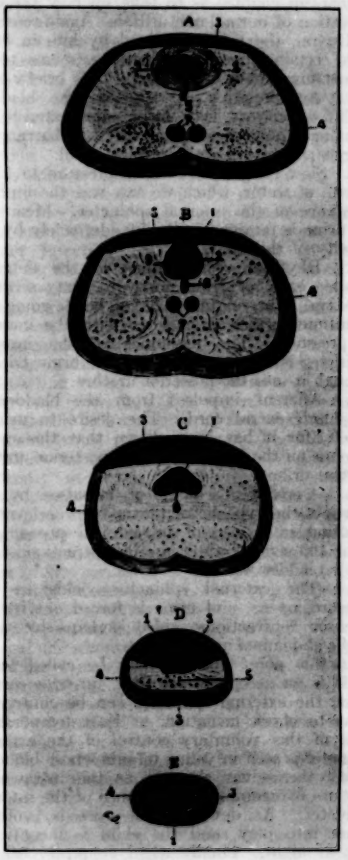

FIG. II. The external urethral sphincter seen in cross sections of the prostate. *A*. 6 mm. below the bladder neck. *B*. 15 mm. below the bladder neck. *C*. 20 mm. below the bladder neck. *D*. At the apex of the prostate. *E*. Guyon showed, in 1901, that, after section of the nervi erigentes and injection of an irritant (silver nitrate) into the bladder, the latter would still contract and expel a part of its contents. From this he concluded that the tonicity of the bladder muscles was in certain conditions independent of all medullary and even of all extra-

vesical nervous influence. This is also the opinion of Hirt, Orth, Kocher, Bernheim, Ehrlich and Brieger, Von Zeissl, Henle, Goltz, Bernstein, Dubois and Landois.

The foregoing description of the anatomy, nerve supply and physiology of the urinary mechanism enables us to take up now the consideration of normal micturition. Again referring to Guyon, the theory evolved by him in 1887, with certain minor modifications, seems to be almost unanimously accepted. It is briefly this:

1. Accumulation of urine in the bladder. "The tonicity is very feeble, the extensibility great and the contractility small" (Albarran and Noguès). Intravesical pressure is nil.

2. Slow rise of intravesical pressure to 15 or 20 cm. of water, which we saw was the limit of resistance of the internal sphincter. Meantime the urine is retained in the bladder solely by the tonicity of this sphincter.

3. Rhythmic contractions of the detrusor muscle, each of from forty to sixty seconds' duration (Sherrington), have been going on meantime, increasing in force with the increase of pressure. The resistance of the internal sphincter is overcome and a little urine trickles through it into the posterior urethra.

4. Afferent impulses from the bladder to the lumbo-sacral cord. The desire to urinate is felt, for it has been shown that this desire depends on the irritation of the posterior urethra by the urine.

5. A reflex discharge of impulses by the nerves of the hypogastric plexus (nervi erigentes), resulting in a rise of intravesical pressure to 70 or 100 ccm. of water, and a contraction of the whole bladder wall.

6. The external sphincter yields to this pressure, opens, and urine is forced out by the detrusor contractions, aided perhaps by those of the abdominal muscles.

At this point volition may be called forth, for it is an accepted fact that, up to a certain point, the external sphincter can be contracted so as to check urination, at least temporarily. Lack of this voluntary control of the external sphincter is seen in young infants whose bladders empty themselves as soon as the intravesical pressure overcomes the resistance of the internal sphincter. As development proceeds, volition comes into play, and the child is incontinent only at night. Finally when voluntary control of the external sphincter is fully established, the desire to urinate is under practically complete mastery, as in the adult, and urination can then be started or stopped at will. It is the result of an automatic natural reflex acquired by education.

Howell states that Mosso and Pellacani have shown that the bladder is very sensitive to reflex stimuli. Psychic and sensory stimulation may cause contraction or increased tone of the organ. It is thus subject to constant change in size from reflex stimulation, and the intravesical pressure will then depend not only on the quantity of urine, but also on the tonicity of the detrusor itself. At a certain pressure stimulation of the sensory nerves occurs, and under normal conditions urination ensues. This will explain how, in conditions of emotional excitement, there may occur a strong desire to urinate with only a little fluid in the bladder.

It was seen in my first article that in tabes we have certain signs and symptoms referable to the bladder. The signs are trabeculation, residual urine and anesthesia of the bladder neck. The symptoms are difficult urination, incontinence, dysuria, urgency, frequency, retention and absence of the desire to urinate. These must all be explained, and the explanation must find its basis, in the description already given of the anatomy and physiology of the urinary mechanism.

I, therefore, offer the following explanation of these signs and symptoms. It is largely a theory built up from the evidence at hand. Were there any definite statements of the condition of the nerves controlling the urinary function in tabes, this theory might be placed on a sure pathological basis. So far as I know, the nerves supplying the bladder have never been studied in tabetics.

Painful micturition and irritability of the bladder neck (seen in certain cases) I consider to be a hyperesthesia, analogous to that seen in diseases of the peripheral nerves in other parts of the body.

Frankl-Hochwart, Bierhoff and Böhme think that the urinary disorders seen in spinal cord disease are a question of true, tonic spasm of the external sphincter, and inability of this sphincter to relax, a weakness of detrusor contraction, or possibly of all three factors.

We can eliminate at once an impairment of detrusor contraction, for it has been shown by many able observers that the activity of the detrusor muscle is a pure reflex, independent of all medullary and extravesical nervous influence. If this reflex contractility does not occur, how, then, can we account for the trabeculation, which is found before any symptom or other sign of bladder disturbance, and which we also saw was, primarily at least, a result of increased work on its part? Now the cause of this extra effort is an obstacle to the stream of urine offered by the failure of the external sphincter to open. Normally when the urine is forced against this sphincter, by the contractions of the detrusor muscle, the latter, together with the presence of urine in the posterior urethra, cause a discharge of reflex impulses and the external sphincter opens. In the tabetic this sensation is dulled or absent, as shown not only by the failure of the external sphincter to open, but also by two other factors. One is the complete lack of sensibility of the posterior urethra which enables the cystoscope to be passed without the least sensation on the part of the patient, even without cocainization. The other is the lack of normal desire to urinate, so frequently seen in tabetics. Some patients lack this sensation to such an extent that they empty their bladders only once or twice in the twenty-four hours, and then more from a sense of duty than of necessity.

When, however, the patient does urinate, the striated sphincter cannot be fully relaxed because of an increased tonicity, or because of paralysis. These factors are difficult to determine because this sphincter is believed to have two kinds of motility, reflex contractibility and voluntary relaxability (Hirt). The brain does not receive in due time the sensation from the bladder. Meantime the climax of the detrusor contractions has been reached, and the tabetic empties his bladder on the downward wave of these contractions (Rehfisch, experimental). Thus the stream is slow and small. As this condition becomes more marked, the patient begins more and more to exert pressure on the bladder by the contraction of the abdominal muscles, thus aiding the action of the detrusor.

But before even the patient has any hint of it, the same difficulty of micturition has been going on in a mild form. The detrusor has been working against an unyielding sphincter and as a result of this extra effort trabeculæ are formed. At first the detrusor can compensate for this obstruction, and, by hypertrophy and hard work, empty the bladder completely. In the course of time this compensation fails, even as heart compensation fails, and we find residual urine. We saw that some patients said they did not feel as if they emptied their bladders. This, then, accounts for this sensation.

To proceed with our theory, nocturnal incontinence occurs from a lack of sensory stimuli from bladder to brain. The bladder fills, contractions occur, the external sphincter is either forced by unusually violent contractions of the detrusor or is reflexly relaxed by them. During the day incontinence occurs less often, or not at all, because with the faculties alert the patient either perceives the desire to urinate and thus contracts his external sphincter voluntarily, or its reflex contraction is unconsciously increased.

Incontinence in tabetics is usually the overflow from a full bladder. It is generally spoken of as ischuria paradoxa. The bladder reaches a certain degree of pressure; this is sufficient to force the external sphincter by the violent detrusor contractions. A little urine escapes, thus lowering the intravesical pressure. Leakage then ceases, until, by the further accumulation of urine, the intravesical pressure is again raised to a point where the external sphincter is once more forced or relaxed and the incontinence recurs.

In somewhat the same way the momentary incontinence occurring with coughing, sneezing or any sudden muscular effort may be explained. The bladder is full, detrusor contractions are going on, the diaphragm becomes fixed, the abdominal muscles contract and compress the bladder. Aided by this pressure the detrusor is able to force a little urine through the external sphincter. This momentarily lowers the intravesical pressure, the brief contraction of the abdominal muscles ceases and leakage stops.

Finally, we must not forget the important factor of incoördination. This occurs in the muscles of locomotion; why not, therefore, in those of urination? It will aid us greatly in explaining wholly or in part the intricate puzzle before us. As Hirt says, "The necessary gradation of dosage of innervation for normal effect is destroyed." The sphincter does not open at the right moment, or with the poor "team work" it closes before the urine has had time to escape. Further evidence of the factor of incoördination is found in the educatability of the muscles concerned in urination, which I shall show later.

Still another factor must be considered in the explanation of these symptoms, namely, urinary infection. It was seen that this occurred, with a concomitant cystitis, in over 50% of cases. We also know that such an infection will cause irritability of the bladder and urgent urination in any individual. Therefore, when the symptoms of bladder infection are superimposed on those caused by the nerve and cord lesions in tabes, we find a doubly complex picture. It may help to explain certain symptoms on the one hand, but *per contra*, it makes the explanation of other symptoms more difficult.

In conclusion, I wish to call attention to the "exhaustion theory" of Edinger, as set forth by Adami and Nicholls. The reparative processes in the specific cells are impaired as a result of some toxin circulating in the system. The neurones which are normally most active, or are most constantly at work, are those which suffer. These are the sensory nerves from the muscles which play an important rôle in the regulation of muscular contraction, and are constantly submitting those stimuli by which we become aware of the condition of our muscular system. The purely sensory nerves which are constantly submitting sensations from the mucous membranes would be likely to suffer and give rise to sensory disturbance. In this way the bladder disturbances may be explained as the result of a destruction of sensory impulses, which that organ is constantly transmitting.

Briefly summarizing the above remarks it can be said that,

1. The bladder is guarded by two sphincters, an internal of smooth fibers, and an external of striated fibers, of which each has its special power of resistance.

2. The function of urination is controlled by branches from the hypogastric plexus (nervi erigentes).

3. The detrusor muscle may contract reflexly without connection with the central nervous system.

4. The urinary disorders of tabes are dependent on, (*a*) a disturbance in the transmission of sensory impulses from bladder, (*b*) incoördination of the muscles of micturition, (*c*) urinary infection.

A BIOGRAPHY OF CHARLES SPON, M.D.*

BY CHARLES GREENE CUMSTON, M.D., BOSTON,
Member of the Medical Historical Society of France, etc.

CHARLES SPON, the son of Mathieu Spon, and Judith Bernard, his wife, was born at Lyons on Dec. 25, 1609. Little is known as to his early education, neither of his life up to 1620, at which time he was sent to his uncle, Charles Spon, at Ulm. His biographers declare that he was particularly fond of Latin poetry, so that his professors already foresaw in him the ingenious author of the "*Myologia heroica carmine expressa.*" His familiarity with the French language, as well as the intellectual midst in which he passed his childhood, undoubtedly contributed to give him his great facility in the study of Latin. However this may be, he preserved during his entire life his great aptitude for this dead language.

He did not remain for any length of time at Ulm, and in 1625 he was in Paris as the disciple of the philosopher, Rodon, whom he left in 1627 to study physics in the Collège de Lizieux. In this institution, which was under the direction of the celebrated Guillaume Mazure, physics and natural sciences were taught under the name of physics. Taking all things into consideration, the preliminary studies in Spon's time were practically the same as they are to-day in the European universities, namely, the study of Latin and letters, philosophy and the natural sciences, only after which could one matriculate in the Faculty of Medicine.

Spon remained at Paris until 1632. He was fortunate enough to study under a coterie of eminent masters. He became especially intimate with Cousinot, who, at that time, had emitted his opinion on the two great medications of the period, namely, diet and bleeding, in the two following works: *Non ergo phlebotamia die critico crisin imminentem remoratur*, Paris, in 4, 1623, and *Ergo dieta plenior securior*, Paris, in 4, 1624. This friendship was of benefit to him inasmuch as when, later on, Cousinot became the first physician to Louis XIV, he obtained letters patent for his former student as quarterly physician to the king. Among other noted men who taught at Paris at this time may be mentioned Pyart, Merlet, Perreau and Charpentier.

* As Guy Patin's letters have long been consulted by both historians and physicians, it was thought that a biography of one of his most constant correspondants, Charles Spon, might be of interest, as little has been published about him. C. G. C.

In 1632 Spon went to Montpellier, where he became on intimate terms with Courtaud, the future adversary of Guy Patin, and with him he admitted the theories of Harvey. After a few months he took the bonnet of doctor and returned to Lyons, but he did not immediately commence to practice there.

His sojourns in Paris and Montpellier revealed to him the rivalry which then existed between the two Faculties, as well as between the theories taught and those who upheld them. This rivalry continued up to the end of the last century and contributed not a little to a wise reserve and a prudent skepticism on the part of the physicians of Lyons. The majority of them, like Spon, had studied at Paris, but, for some unknown reason, most of the degrees were taken at Montpellier, a fact that is made evident when one consults the works published at this time, because one meets, under the name of the author, D.M.M., more frequently than D.M.P.

Although Lyons, at this time, had no university, it possessed, on the other hand, a College of Physicians, whose reputation dated back many years, and although somewhat of a digression, a few words relative to this institution do not seem out of place, and what is to follow regarding it is quoted from Brossette's work entitled, "*Nouvel Éloge de la ville de Lyon*," which was published in 1711.

"The college of medicine of Lyons is illustrious, not alone because of its antiquity, but also on account of several learned physicians who have belonged to it, among which, without speaking of Abascantus, praised by Galen and Andromacus, one may mention during the latter centuries Gui de Chauliac, Simon de Renodis or of Pavia, François Rabelais, Henri Corneille Agrippa, Michel Nostradamus, Joseph Duchesne, known under the name of Quercetan Jacques Daléchamp, Charles and Jacob Spon and several others."

"Physicians who wished to enter this college must give proof of their capacity by public examination, which is carried out with much exactness and severity, so that it frequently happens that certain candidates are refused, although they may have obtained the degree of M.D. from some university. The physicians of Lyons take the title of professor, because they give public lectures on anatomy, surgery and pharmacy. We have several excellent works on medicine as well as on other subjects composed by the physicians of Lyons belonging to the college."

In point of fact, the College of Physicians is not as ancient as Brossette would lead one to believe, its foundation, in all probability, only dating back to 1540. In 1576 this institution was chartered by Henry III, while its statutes were confirmed in 1577. In order to become a member, it was not alone enough to pass the examinations, but the candidate must have shown that he had practiced for two years in some village in the neighborhood of Lyons. Spon, consequently, submitted to the rule and commenced practice at Pont-de-Vesle, a small town situated about a league from Mâcon.

In July, 1635, Spon came to Lyons and, on Aug. 7, in the same year, he was admitted to the learned assembly. It was from the time of his entrance into the College of Physicians that Spon commenced his true career. Favored by a large practice, which later on he confided to his son, Jacob, and one of his nephews, Charles, he received in 1645 letters patent as quarterly physician to the king. This distinction, much more honorary than beneficial in its pecuniary aspects, was accorded him, as we have already said, through the efforts of his former master, Cousinot. The care of his patients did not take up so much of his time as to prevent him from giving up several hours each day to his correspondence and to the publication of his many works which saw the light of day at Lyons. As a bibliophile he also exercised considerable influence.

The certificate of the "bourgeosie" which the consulate conferred upon him at the commencement of 1639 also contributed to increase his notoriety and facilitated his relations with the celebrities of his time. Above all should be mentioned the friendship which united him to Guy Patin, and it is by the intermediary of the latter that it has been made possible to penetrate a little into the private life of Spon. Spon's wife was greatly admired by Patin; she belonged to a Protestant family for a long time established at Lyons, her maiden name being Marie Seignoret. One of her brothers was a minister of the Reformed Church. She married Spon in 1643.

From 1645 Spon's life continued without any incident worthy of note. However, his nomination to the title of "vice decanus et procurator inclyti collegii medicorum lugdunensium" should be mentioned. The word "vice" is there merely to save appearances, because, being a Protestant, Spon could not be dean, and he did not feel that he could give up his religion simply for the title in full, but it may be said that he fulfilled his functions in a manner satisfactory to all. There exist several letters addressed to him in which he is given the full title of dean.

In spite of all these honors, the latter years of his existence were passed in sadness. His relatives and friends in Germany were ruined by war, while those of his own religion in France were closely watched. His son returned after a long absence in foreign lands, where he had left both his health and his fortune. All these circumstances undoubtedly contributed to hasten his death, the cause of which is unknown, but in a letter written to Abbé Nicaise, his son, Jacob, refers to the death of his father in the following terms: "He died universally regretted by all the good people and mourned by the poor, to whom he never refused his help. Ill for four months, he only took to his bed in the beginning of January. God preserved his mind up to his last breath."

He died on Feb. 21, 1684, as is shown by the following document: "1684, No. 1797. Charles Spon, Doctor of Medicine, died at Lyons on Feb. 21, 1684, and was buried the 22d of the same month at l'hôpital du pont du Rhône, the ordinary cemetery for those of the reformed religion, in presence of M. M. Brière, Seignoret, and Louis Gérard."

Although this biography is extremely short and undoubtedly far from complete, it is made so simple because only what is authentic of Spon has been given. This distinguished physician certainly played an important part by his writings and correspondence in the medical history of Lyons, as well as by his character and personal qualities.

Although Spon passed his life among savants, he never lost his love for Latin poetry and many admirable verses have been penned by him. In 1636 he commenced to write the maxims found in the Aphorisms of Hippocrates, but having discovered that others before him had had the same end in view, he never published this work. In 1661 he transposed the same author's book on Prognosis into Latin verses, publishing it under the title of "*Sydilla medica.*" Another work which had quite a success is his "*Myologia heroica carmine expressa.*" This work, upon which he worked during his entire life, would probably never have been printed if his son, Jacob, had not given the manuscript to Leclerc and Manget, and these authors, who published the well-known classical work in two volumes, entitled "*Bibliotheca anatomica,*" included this work among others by celebrated men. The work was published at Geneva in 1699.

This poem on the anatomy of the muscles is divided into two parts, the first being an enumeration in hexameters of all the muscles belonging to man, while the details are given in the second part, entitled, "*Musculorum microcosmi origo et inscrito,*" this being divided into twenty-three chapters. In this second part the author adopts the rhythm found in certain of Horace's Odes. As an example, his description of the muscles of the forearm may be given:

Est supinantum radios duplex pars
Longius necnon brevius duplexque
Diga pronantum puta tetragonus
Atque rotundus.
Musculas pronans radium rotundus
Condyli interni interiore ab ora
Brachii surgit mediaque radique
Parte quiescit.

Another work by Spon entitled "*Recueil de constitutions médicales*" contained his experience in the practice of medicine, but the manuscript, which had not been published up to the time of his death, fell into the hands of his son, Jacob, and was lost along with the letters comprising the correspondence of both the father and son.

Spon rendered great service to science by giving his attention to the publication of medical works printed at Lyons, particularly Sennert's letters, the observations of Schenkius, and, above all, Cardano's works. Schenkius, who was professor at Freiburg, and died in 1598, had published his works in the first place at Basle and at Freiburg, respectively, in 1584 and 1597, the whole comprising seven volumes. They were again published

at Frankfurt in 1600 and at Lyons in 1644, under the care of Spon.

As has already been said, he also edited Sennert's work. This writer enjoyed a much greater renown than Schenkius. He was born at Breslau in 1572, receiving the degree of doctor at Wittemberg in 1602, and later became professor of medicine at this university. He is supposed to have died in 1637 from the plague. His writings are of particular interest because he was the first to introduce chemistry into medical studies and endeavored to conciliate the principles of Paracelsus with those of Galen. The third author whose works were published by Spon was Cardano. The Lyons' edition, published by Spon, is dated 1663, and has for title: "*Cardani Hieronymi Opera omnia, cura Caroli Sponii Lugduni sumptibus Joannis Antonii Huguetan et Marci Antonii.*"

Lastly is to be mentioned a volume entitled: "*Appendice chimique à la pharmacopée de Lyon.*" This work, which was published under the auspices of the College of Physicians, in 1628, bears no author's name, but a second edition appeared in 1674 under the following title: "*Pharmacopea Lugdunensis reformata mandato et cura inclyti collegii medicorum Lugdunensium Lugduni Gallorum MDCLXXIV, Ejusdem collegii sumptibus excusa, typis Jacobi Faeton.*"

The last section of this pharmacopoea is, "*Appendix de medicamentis chymicis,*" and this appendix was written by Spon himself. This appendix was also printed in the first edition, but it consisted of only three short chapters. The fourth chapter, *De calcibus*, etc., was entirely due to Charles Spon.

To give a description of Charles Spon's correspondence and the influence that it had upon medical science of the time would be far too long, although full of interest.

In closing, however, one name among Spon's correspondents which has become almost inseparable with his should be mentioned, viz., Guy Patin. It is most curious to see the physician of Lyons united in friendship with two men who passed their lives in opposing each other as did Courtaud and Patin. The latter, with a mind filled with preconceived ideas and an open enemy to all progress, would hardly appear the sort to be a confidant of a man as liberal as was Charles Spon. Chance had brought them together in Paris and they continued their relations formed there by an active correspondence. The letters of Charles Spon have unfortunately been lost, but Patin's have luckily been preserved. From 1642 to 1664 the latter did not cease to write his friend.

Courtaud was born at Montpellier and received the degree of doctor in 1611. Being the nephew of Heroard, chief physician to Louis XIII, he received letters patent as quarterly physician to the king, but for reasons which need no discussion here he was obliged to sell his position and establish himself at Montpellier. Renowned for his polemics, Courtaud should more particularly be known for the service that he rendered in the teaching of medicine at Lyons, because it was through him that Charles Spon received his knowledge of the works which appeared at the time and was informed of their good qualities and defects. Courtaud was extremely learned and, consequently, was well placed to instruct Spon in the value of many medical works.

Clinical Department.

A CASE RESEMBLING MYOTONIA OCCURRING IN AN ADULT, DUE TO THE TRICHINA SPIRALIS, WITH THE PATHOLOGICAL FINDINGS IN THE MUSCLES.*

BY ISADOR H. CORIAT, M.D., BOSTON.

THIS case is reported rather fully because of the occurrence in an adult of a symptom-complex which is usually found only in childhood, of certain difficulties in diagnosis and finally of the interesting histological findings.

The patient, a healthy man seventy-one years of age, was referred to me by Dr. Metzger, of Lynn, Mass., for a peculiar stiffness of the leg muscles which interfered with his ability to walk. It is stated that the father of the patient, who was a blacksmith, developed an atrophy of the arm and hand muscles following a period of overwork at his trade, the condition persisting until his death, at the age of seventy-two. This localization of the muscular atrophy is an intersting confirmation of Edinger's theory of over-exertion. It appears, however, that the muscular atrophy in the father was a mere coincidence, as the type of disorder found in the son was distinctly non-hereditary, a pure myopathy, due to a specific infection and not to any atrophy of the motor cells of the spinal cord. Eight years before coming under observation there was a history of a severe gastro-intestinal attack. Shortly afterwards a stiffness was noticed in the right leg, followed by a weakness of the muscles of the right foot. Finally, the left leg and foot were likewise affected. There was usually no difficulty in starting to walk, but after a short time, or in excessive fatigue, there arose a sensation of tightening in the calf muscles which made further walking impossible. A short rest, however, restored the contractile ability of the muscles. In bicycle riding the same difficulty took place; he was able to go only a short distance, when further pedalling became impossible.

The neurological examination showed the following. The calf muscles were thin and flabby, the measurement for the right calf being 29 cm., for the left calf 30 cm. Occasional fibrillary twitchings were noticed in these atrophied muscles. The foot could be extended and flexed rapidly and easily, but after a few minutes these movements became slower and more difficult and then almost ceased, the calf muscles at the same time becoming hard and rigid. After walking a few steps the gait became stiff and the phenomenon of rigidity of the calf muscles was again found to take place. This rigidity disappeared in about a minute after the contractions had ceased. There was no difficulty in starting to walk or in the initiative voluntary movements. He could also arise quickly from a sitting posture. There was no overdevelopment or hypertrophy of the musculature. The bladder and rectum, the muscular movements of the upper extremity, the facial muscles,

* Read before the Mt. Sinai Hospital Clinical Society, Oct. 13, 1910.

the muscles of mastication and the ocular muscles were unaffected. It will be noticed that the muscular rigidity took place only after a number of muscular contractions and not at the beginning of voluntary movements, thus partially differentiating the condition from myotonia congenita (Thomsen's disease).

It was not a true intention rigidity and, therefore, this portion of the symptom-complex was only partially allied to a genuine myotonia. Further clinical investigation, however, brought out a more marked resemblance, particularly concerning the nature of the electrical reactions and the muscular contractions after mechanical stimulation.

On striking the calf muscles briskly with a percussion hammer, the muscular contractions were seen to spread slowly in waves from bundle to bundle. According to Jensen, who made myographic studies on the nature of this phenomenon, the myotonic muscles very slowly relax, the process consuming more than eight seconds, while the relaxation of normal muscles consumes only about 0.2 of a second. All the calf muscles (gastrocnemei, solei, peronei and anterior tibial group) reacted only to a strong faradic current. The contractions, however, were slow and sluggish, and after removal of the electrodes a long undulating contraction, spreading from one muscle bundle to another, remained for several seconds (Erb's myotonic reaction). Electrical stimulation of the nerve trunks in the popliteal space produced the same slow contraction waves in the calf muscles.

The knee-jerks were somewhat exaggerated, the plantar reflex normal and brisk, there was no ankle clonus and no Babinski. The Achilles jerks were absent. The pupils and ocular movements were normal. There was no nystagmus. Sensory disturbances were absent. An examination of the blood showed the percentage of eosinophiles to be normal.

Under local anesthesia a small piece of muscle was removed from each calf. The pieces of excised muscle were hardened in Zenker, imbedded in paraffine and stained with the connective tissue stain, hematoxylin-eosin and osmic acid. With the latter, no fatty degeneration of any of the muscle fibers could be made out. The connective tissue stain revealed encapsulated larvæ of the trichina spiralis.

The most interesting histological findings were in the muscle fibers. In my study of the muscles I compared the condition with some of the most recent advances in muscle histology, particularly the work of Meigs. These muscle fibers were in all stages of progressive degeneration. They seemed to fall into several groups: A few normal fibers, hypertrophied fibers with some increase of nuclei, progressive increase of nuclei with diminution of sarcoplasm and finally only a sarcolemma sheath enclosing a mass of nuclei. With a high power these latter were seen to be round mononuclear cells, containing a small nucleus and a large amount of protoplasm.

In these cells, mitotic figures could be seen. Because of their infiltrating and invading character, being found in largest number where the destruction of the sarcostyles was the greatest or where only a sarcolemma sheath remained, these cells were probably of the nature of scavenger cells (phagocytes), myophages they might appropriately be called. These cells seem to be different from the normal, spindle-shaped muscle nuclei, as these latter lie directly and singly beneath the sarcolemma sheath, whereas the scavenger cells were scattered in clumps all over the muscle fibers. In some of the muscle fibers which were cut transversely nothing could be seen but a hollow ring with a few fibers at the periphery. In the hypertrophied fibers the sarcostyles were found to be thickened and swollen, whereas in the atrophied fibers the sarcostyles were thin and very indistinct. Within the sarcolemma sheaths, masses of broken up sarcostyles were found, or sometimes the sarcolemma sheath was empty except for masses of scavenger cells. With a high power and a dim light the cross striations could be clearly distinguished even on the degenerated and atrophied sarcostyles, while in the hypertrophied sarcostyles the cross striations had entirely disappeared, the fibrils were swollen and took a faint, diffuse stain, resembling the condition seen in acute and subacute myositis. Occasionally other cells were seen, sausage-shaped, filled with dark granules and containing two or three nuclei. These were probably mononuclear cells in a process of rapid division. Eosinophile cells were absent, but these seem to have been found only in the acute and subacute conditions and not in the chronic stages of the disease.

The pathogenetic agent in the condition and the cause of the pathological findings in the muscles was undoubtedly the trichina spiralis. It is well known that the encysted larvæ of the parasite may remain in the muscle for years. Our case showed the typical gastro-intestinal disturbances as a premonitory symptom of the disease, and closely on this, the peculiar muscular stiffness followed, resembling a genuine myotonia.

The trichina spiralis occurs in three stages: The adult, which is found only in the intestine or its lymphatic spaces; the embryo, which wanders from the intestine (where the females deposit their young) either through the lymph or blood to the striated muscles and, finally, after the embryo enters the muscle fibers, it develops into an encysted larva. When muscular invasion occurs, the parasite then excites its irritative action and causes the fiber degeneration and nuclear proliferation. Not only may the skeletal muscles become involved, but the heart muscles as well, producing an acute myocarditis, the so-called trichinosis heart.

Other reported cases of muscular invasion by the trichina spiralis, when the muscles were examined, have shown similar findings. Histological studies of the muscle changes in chronic trichinosis are rather rare, however, as compared with the investigations on the acute type.

Even in Stäubli's extensive monograph on trichinosis, there is no description of the muscle findings in the chronic or quiescent stage of the disease. Neither has the literature furnished any description of the resemblance of the muscle phenomena in quiescent trichinosis to certain symptoms of the pure myopathies, such as myotonia.

Lorenz has reported three cases in various stages of the disease. He found, in the acute and subacute condition, cellular infiltration and a marked increase of sarcolemma nuclei, the formation of vacuoles, diffuse muscle degeneration, sometimes fatty changes and eosinophile cells. There was no fragmentation of the sarcostyles. In what he terms obsolete or quiescent trichinosis there was also found an increase of the sarcolemma cells, atrophy and degeneration of the muscle fibers and, in addition, granulation of the protoplasm and fragmentation of the fibrillæ.

In acute experimental trichinosis, Soudake-

witch found an increase of nuclei in the muscle bundles, while the sarcostyles retained their striated structure. If the process was allowed to progress, however, it was found that the muscle striations disappeared, while the number of nuclei increased. He refers to this increase of nuclei as muscular phagocytosis.

Ehrhardt has also studied the histological findings in experimental trichinosis. He found marked changes in the nature of the protoplasm, as shown by the microchemical reactions, fatty, granular and waxy degeneration, swelling of the fibers and an enormous increase of sarcolemma nuclei, in some cases with mitotic figures. The voluntary muscles of man showed less fatty degeneration and less mitoses of the nuclei than those of rabbits.

Brown studied four acute cases of trichinosis, and in addition to the marked eosinophilia in the blood he described the following changes in the muscles. There was marked fragmentation of the muscle fibers, which may break up in the long axis of the fibers into separate fibrillæ or into bunches of fibrillæ. Sometimes the fragmentation was transverse, thus splitting the muscle into distinct disks. Whether the fragmentation took place at the membrane of Krause or at the plane of Henson could not be determined. There was slight thickening of the sarcolemma and marked nuclear proliferation even where no parasites were seen. There were many polymorphonuclear cells between and within the fibers, and many cells whose protoplasm showed a marked affinity for the eosin stain. While these cells were probably phagocytic in nature, yet no ingestion of rod-shaped bits or disks could be seen.

Without again going into detail, it will be noticed that the muscle findings of the various observers corresponded almost exactly with the results of the examination in our case. We refer particularly to the degenerative changes in the fibers, the presence of large numbers of foreign cells, probably phagocytic in nature, and the marked increase of the sarcolemma nuclei. The nuclear degeneration and the cellular proliferation is undoubtedly caused by invasion with the larva of the trichina spiralis, the latter being a pathological process analogous to the lymphoid and giant-cell formation of the tubercle bacillus. In fact, many cells in our case were sausage shaped and showed many nuclei, resembling the giant cells in tubercular processes.

This infiltration and increase of nuclei has also been found in other pathological conditions where the muscles were affected. The condition is the same either in the pure myopathies or where the muscular changes are due to trophic influences from the central nervous system.

In subacute polymyositis, granular degeneration of the muscle fibers with great increase of nuclei has been found. This increase of nuclei and muscular degeneration has also been pointed out as occurring in amyotonia congenita or Oppenheim's disease (Collier, Holmes, Wilson, Skoog), in some cases of progressive neural muscular astrophy (Cassirer and Maas), and in Thomsen's disease (Schiefferdecker and Schultze). In fact, Dejerine and Sottas claim that the first phenomena of Thomsen's disease is a hyperplasia of the nuclei, probably due to a disease of the sarcoplasm. The mixture of atrophied and hypertrophied muscle fibers in our case is of interest as many of the pure myotonias have also shown a transition into muscular atrophy. In fact, such cases have been reported by Frohman and Hoffman in certain infantile hereditary forms of progressive muscular atrophy. It would seem from this fact alone that we can no longer interpret the myotonias as diseases of metabolism caused by toxic products, from changes in the parathyroid glands or from kreatinin poisoning, as Bechterew and Lundborg have done. They are rather pure myopathies due in one case to a specific irritative agent like the trichina spiralis, in the other to an unknown pathogenesis probably of a trophic nature, which acts on the primitive sarcostyles of the muscle tissue. In conclusion I wish to thank Dr. Leary, of the Pathological Department of Tufts College Medical School, for the preparation and staining of the specimens, and also for many valuable hints on the histopathology of muscle fiber.

(Continued from No. 25, p. 958.)

THE TUBERCULIN TREATMENT OF PULMONARY TUBERCULOSIS IN OFFICE AND DISPENSARY PRACTICE.

JAMES ALEXANDER MILLER, A.M., M.D., of New York.

Tuberculin is now generally regarded by physicians who have had sufficient experience with it as a valuable aid in the treatment of pulmonary tuberculosis if used

in connection with other accepted methods. The method of administration is the so-called "clinical method" of producing tuberculin tolerance, the aim being to gradually accustom the patient to increasing doses of tuberculin, beginning with a very small amount easily tolerated and proceeding over a long period of time to large doses without the production of any reaction.

There is no material advantage in any one of the usual preparations of tuberculin, the active principle apparently being the same in each.

In selecting suitable cases for this treatment in the dispensary, it should be borne in mind that for incipient cases sanatorium treatment is always advisable and hospital treatment for advanced cases.

Tuberculin finds its widest usefulness in the intermediate cases for whom there is no adequate institutional provision. As the treatment is one of active immunization, it requires an ability to respond on the part of the patient, so that it should never be used in cases where the general condition is very poor or where there is fever.

A preliminary rest treatment, in order to build up the general condition of the patient, is almost always desirable, and throughout the treatment every effort must be made to carry out the general principles of the hygienic and dietetic treatment. Injections are given twice a week on an average, and the beginning dose varies from 1-100,000 mgm. to 1-10,000 mgm., and the progression of dosage depends on the clinical symptoms. The highest dose to be given depends upon the needs of the patient, in many cases reaching as high as 1 gm., with many others getting as good results from 1 mgm.

The time element is important, at least six months and often eighteen months being necessary to complete the course of treatment.

Often repeated courses of tuberculin are necessary in chronic cases. The results obtained in seventy cases treated at least three months in dispensary and private practice in New York City showed that 51.4% were either cured or their disease arrested, and that although these cases were treated over a period of five years, 58.5% of them are now well and in active life. This is especially suggestive as 87.2% were advanced cases.

With sufficient experience and proper precaution tuberculin treatment can be carried on quite as satisfactorily in the dispensary as in the sanatorium.

H. M. King, M.D. Results seem to justify further efforts in this direction.

Dr. Solis Cohen, Philadelphia, said that he had a very prolonged experience with tuberculin, and gave the first injection of tuberculin before his class at the Jefferson Medical College in Philadelphia in the early eighties, upon a patient with advanced tuberculosis of the larynx. Ten years ago the man was well and was a successful ranchman in Wyoming, but he has not heard from him since. Another patient treated fifteen or sixteen years ago for ulcer of the larynx had his disease arrested after several months of treatment, and two years later had his life insured in the Mutual Life Insurance Company of New York for $100,000. Other cases are still living at different periods of five to fifteen years or more, and doing well. He generally used the old tuberculin of Koch, beginning with minute doses, generally increasing them, as described by the last two speakers, and studying the patient rather than the disease. When he studied medicine some fifty-five years ago, it was the custom to apply fly blisters as near as possible over the site of the lesion of phthisis. Nothing was known of the bacillus tuberculosis at that time, but many of these cases improved, and since the tuberculin and serum treatment have been applied he has thought that possibly the absorption of some of the serum raised by those blisters was beneficial in the same manner as the serum when injected under the skin; acting on this principle it has been his custom with many patients to blister the chest below the clavicle, taking care that the blister shall not burst, so that the patient's own serum may be absorbed on the same principle as the autogenous methods, and he wished to give testimony as to the advantage of this method in properly selected cases and under proper precautions.

Dr. Bowditch, Boston, ranked himself in the class spoken of by Dr. Miller who tried it immediately after it was given to the public, and then abandoned it, being impressed by the statement that there was danger of causing disseminated tuberculosis. In recent years, feeling that possibly he might be withholding the treatment from some who might be benefited, he, in association with Dr. Griffin, applied the treatment on some patients, who were not progressing under the usual treatment, and the results were so startling that now in addition to beginning on patients who were not doing well under dietetic and hygienic treatment, he begins on the incipient cases also. At present he is greatly impressed with the value of tuberculin.

Dr. Griffin, Sharon, Mass., cited two cases in which Dr. Bowditch and himself had used tuberculin treatment, and briefly reported on twenty-eight cases which have had this treatment at Sharon and have now been discharged for more than a year. Of these twenty-eight patients, six have died, — two were really too far advanced to warrant advising it, but took it at their own request; four others were advanced cases and were treated as a forlorn chance, and four others are not doing particularly well. This leaves eighteen out of the twenty-eight cases which are doing well, which seems to be a comparatively good record, especially when it is considered that all were more than incipient cases. It is well known that the tuberculin will do no harm, and it frequently will do good.

Dr. Nagle, Boston, did not wish to be considered too enthusiastic about vaccine therapy, but believes that it is a valuable adjunct in treatment, and laid emphasis on the importance of the proper preparation of the vaccines and the proper method of giving them.

Dr. Minor, Asheville, N. C., considers tuberculin valuable when used selectively, but all cases do not do well on it, and some cases with the greatest care are unable to take it. He advised great care in the selection of cases, and warned against its dangers when used promiscuously.

Dr. Johnson, Paterson, N. J., said that he would judge that tuberculin has been successful in a number of cases, but the important consideration to the otologist is what can be done with the autogenous or stock serum for the destruction of bacterial elements which enter into ear diseases. Few of the cases which have come under his observation have been successful. While not wishing to deprecate the value of experiments in this direction, he is still waiting and hoping for reports of results which will seem to make it desirable for these agents to be used more generally.

Dr. Casselberry, Chicago, was impressed with Dr. King's statements in regard to the pronounced favorable effects of tuberculin on laryngeal conditions in pulmonary tuberculosis; if in tuberculin we have a remedy which will have in any considerable percentage of cases such effects as reported by Dr. King, a great advance has been made. He was also impressed with Dr. King's statement that in cases where he got very pronounced reactions from a larger dose than was intended, the effect was good. He had observed this himself in making the tuberculin test when it was given for the purpose of producing a general reaction —

weeks and even months afterward there had been marked improvement in the larynx. He had observed this, but did not trust to his own observation, and gave the credit to other circumstances. Dr. King has attributed the improvement to tuberculin, and there seems reason to believe he is correct. If the men who treat large numbers of pulmonary cases would always take note of the conditions of the larynx and the effects on conditions there produced by tuberculin treatment, much benefit would doubtless result.

DR. DUNN, Asheville, N. C., said that it is just such good conservative papers as those presented which help. The tuberculin cause has been more damaged by optimisms than by anything else. He always examines the larynx, and has been particularly impresed with the improvement taking place in distinct laryngeal involvement; this is not so striking in advanced cases where there are marked destructive changes. He has watched for the reactions, and has in so many instances seen the beginning of the improvement in the laryngeal reaction that he is convinced of its association with the reaction. He has used various forms of tuberculin, but the immediate results have been practically the same with all. He is very conservative in regard to the value of tuberculin and does not consider that sufficient time has elapsed to form a positive opinion regarding it, but at present he considers it a more or less valuable adjunct to treatment.

DR. I. H. HANCE, Lakewood, N. J., cited an abstract from an article written by a Frenchman which was in line with what had been said about auto-inocculation — in treating pleuritic effusions he withdrew some of the serum and re-inoculated the patient, and had treated five or six cases in this way. This seemed to be in accord with what Dr. Cohen had said about leaving the serum under the blister for reabsorption and auto-inoculation that way.

XII. TRANSPLANTATION OF A RIB CARTILAGE INTO THE NOSE IN A CASE OF NASAL DEFORMITY.

D. CROSBY GREENE, JR., M.D. Read by title.

In the correction of deformities of the nose, characterized by sinking and flattening of the bridge, there is a useful field for the transplantation of cartilage. It has been demonstrated that unless cartilage is transplanted with its perichondrium, it does not grow in the locality, but becomes gradually absorbed. For this reason the material derived from submucous resection of the septum is not usable. Costal cartilage may readily be obtained without injury to the individual, and was used in the case reported. A young man of twenty-two had received an injury in football eight years previously. The nose was struck by a blow across the bridge, which drove in both nasal bones, flattening them. This was followed by an abscess of the septum, with almost complete destruction of the cartilaginous septum. The result was a symmetrically flattened broad nose, with a membranous septum anteriorly. At operation, a chamber for the introduction of the cartilage was prepared by an intranasal incision of the mucous membrane of the septum, parallel to and just behind the muco-cutaneous junction. Through this incision the layers of membranous septum were separated, both in front and behind. The chamber thus formed was enlarged backward and upward over the nasal bones. Simultaneously with this operation, the cartilages of the eighth and ninth ribs were exposed by an oblique incision over their distal ends, and carefully freed from their attachments of muscle and fascia. The size and shape of the piece of cartilage to be used were determined by first fitting into the chamber made in the nose a piece of sterilized leather. This leather was trimmed to the desired shape, and then a piece of rib to match it was removed and placed in the nasal chamber. The wound was closed with a single suture. Four months after operation there was no evident tendency of the cartilage to become absorbed.

No discussion.

XIII. SYPHILITIC STENOSIS OF THE OROPHARYNX.

By J. M. INGERSOLL, M.D., Cleveland, Ohio.

The difficulty in preventing the contraction of syphilitic scar tissue is well known. Syphilitic stenosis of the oropharynx tends to interfere with respiration and deglutition.

In the case reported by the author, the syphilitic scar tissue extended across the oropharynx, uniting the lateral and posterior walls of the oropharynx with the tongue. About in the center of this scar tissue there was an opening ½ cm. in diameter through which the inspired air and food must pass. The opening was so small that it was impossible to secure a view below it. The breathing was labored. The patient had been losing flesh constantly and was quite weak and emaciated.

Incisions were made through the scar tissue at various times and bougies and specially prepared metal tubes were given to the patient to use in preventing the contraction of the scar tissue. The patient, however, failed to carry out the dilatation regularly and there was a constant tendency for the original condition to return.

Similar cases reported by Dr. B. F. Curtis, Dr. G. A. Leland, Dr. C. K. Briddon and Dr. W. H. Battle were cited.

A bibliography was also given.

DR. JOSEPH H. BRYAN, Washington, said that these are the most troublesome cases that the rhinologist has to deal with and that he has never had a successful case; every one has had recurrence of the adhesions, and it seems impossible to give the patients any complete relief from their troubles. He has had cases go along for six or eight months, possibly a year, and still contraction has taken place and the conditions have been almost as bad as they were originally. He had tried the flap operation, but the result was not very satisfactory.

XIV. REPORT OF THREE CASES OF LYMPHOSARCOMA OF THE NASOPHARYNX AND TONSILS, WITH RESULTS OF OPERATIVE AND MEDICINAL TREATMENT.

By CLEMENT F. THIESEN, M.D., Albany, N. Y. Read by title.

In one of the three cases, that of a boy aged fourteen years, the growth was primary in the nasopharynx. Diagnosis confirmed by laboratory examination of pieces removed under cocaine. Nasopharyngeal growth removed under ether. No recurrence in nasopharynx, but soon after operation growth of left tonsil developed with a large rapidly growing metastasis in left side of neck. Boy died several months after operation.

In second case, a man aged forty-eight years, the growth was apparently confined to the left tonsil, a large nodular mass. Laboratory diagnosis — lymphosarcoma.

Operation under cocaine anesthesia; growth including the tonsil dissected out. Not much bleeding. No return in site of operation, but growth in larynx six weeks after operation with great dyspnea. Tracheotomy performed. Patient now in good condition.

Growth in larynx not increasing in size. Full doses of arsenic internally apparently having good effect.

In the third case, the sarcoma was confined to the right tonsil. Patient, a man aged thirty-two years.

Laboratory diagnosis — lymphosarcoma. Growth including tonsil dissected out. Patient in good condition at present writing. Apparently no involvement of glands of neck.

XV. OBSERVATIONS OF THE VARIETY OF GERMS PRESENT IN WOUNDS FOLLOWING OPERATIONS ON THE FAUCIAL TONSILS.

By Alexander McCoy, M.D., Philadelphia. Read by title.

In order to see at first hand if there were any predominating organisms in the pseudo-membranes which form over the exposed surfaces after tonsillotomies and tonsillectomies, cultures and smears were made from these membranes in twenty cases operated upon in the last few weeks. These cases were operated upon in groups of from three to six. Many of them had been associated in the same ward for two or three days before operation. The others were brought to the hospital the morning of the day that they were to be operated upon. They were kept in the hospital on an average of about five days. The cultures were taken by drying the area to be cultured with a sterile cotton swab; then, quickly applying a second sterile cotton swab, turning it once or twice and pushing up part of the pseudo-membrane, this was cultured on Loeffler's blood serum media and incubated twenty-four hours. Smears were immediately made from this same swab. In a number of the cases cultures and smears were made from both sides of the pharynx. Five of the cases were cultured on the first day after operation, nine on the second day, four on the third day and two on the fourth day. The smears all showed the usual polymorphonuclear and epithelial cells. The bacteria were numerous and very variable. In all the smears there were cocci. In two spirochetes and long thin fusiform bacteria were seen, and in two irregular bacteria with beadings resembling polar bodies were present. There were in most all a number of the varied forms of mouth bacteria not in such numbers as to have any definite significance. The cultures showed nothing significant between those taken early and those taken on the third and fourth days, and there was nothing definite between those from the children that had played together for a few days previous to operation and those who were not in a ward together until after operation. Two of the cultures were mostly streptococci. Nine were mostly streptococci and staphylococci. One showed the predominating organism to be a short stout spore-bearing bacillus. In another the predominating organism was a short stout unidentified bacillus singly and in pairs. In nine of the cultures there was no predominating organism, but colonies of cocci and bacilli common in the mouth. In four of these, however, a large diplococcus was found, and in two, irregular beaded bacilli. In one culture there were proteolytic colonies which digested the blood serum. In none of the cultures were Klebs-Loeffler bacilli found. From the cultures of these twenty cases we conclude that there is no predominating organism in the pseudo-membranes; that the ordinary mouth bacteria are to be found in all of them in variable quantities, the cocci being most numerous, and that the cultures will more often show staphylococci and streptococci, probably due in part at least to their greater hardiness on artificial media.

XVI. REPORT OF A FATAL CASE OF ASPHYXIA DUE TO PRESSURE ON THE TRACHEA AND BROUGHT ABOUT BY A TUBERCULOUS MEDIASTINAL GLAND.

Cornelius G. Coakley, M.D.

Dr. D. Bryson Delavan, New York, cited his experience with a similar case. The patient was a beautiful well-nourished child who had been seized with so severe a dyspnea that tracheotomy had to be performed. The tracheotomy had not been very well done and had not succeeded in relieving the breathing, which was possibly excusable under the conditions under which it had been performed. Under anesthesia a very careful examination was made, and an obstruction was found in the middle part of the trachea. There had been severe spasm of the larynx in addition to the pressure on the trachea. Of course the tracheotomy relieved the laryngeal obstruction. The child had a high temperature following the operation and died eight days later. Autopsy showed a tuberculous lymph node pressing on the trachea.

Dr. Chevalier Jackson, Pittsburg, said that the case was an exceedingly interesting one. We seem to be gradually eliminating, one after another, the things which used to be classified as status lymphaticus. These conditions are now being analyzed, and so work as Dr. Coakley had done is going to discover their causes. He also cited the case of a child in which a tracheotomy had been unsuccessful, and in which autopsy showed that both lungs were tubercular. In this instance a lymph gland had broken down and burst into the bronchus. It was a very unusual case. With such men as Coakley and Halsey working along these lines these cases will be differentiated.

Dr. Ingals, Chicago, said that the case recalled to his mind one which, although not exactly apropos, not being tubercular, yet had many of the symptoms of Dr. Coakley's case. The child was brought to the city with an almost typical history of foreign body in the bronchi, a sudden paroxysm of cough coming on at irregular intervals, the child almost suffocating at times. Nothing was shown by the x-ray. The child was placed on the table and ether started with a view to bronchoscopy, but the breathing stopped and the child could not be resuscitated. Later a post-mortem was secured, and a large thymus was found, part of which was adherent very low down, which was evidently the cause of the trouble.

Dr. Solis Cohen, Philadelphia, reported a case which had been referred to him, after examination by another laryngologist, who reported it to be a tumor lymphaticus. He saw a tumor, but as the child was not suffering much at the time, he gave it a placebo and made arrangements for more complete examination the next day, but it was seized with another attack and died. He asked Dr. Coakley to describe the character of the pressure. He had seen some cases of thymus gland pressure where as soon as incision was made the relief was so great that the dyspnea ceased.

Dr. B. W. Shurley, Detroit, said that the case interested him from another point of view. Before the days of bronchoscopy it occasionally happened that one saw cases of apparent laryngeal dyspnea with a long series of intubations where the tube was passed with absolutely no relief. All are familiar with such cases, yet the textbooks scarcely mention the presence of mediastinal disease in children. The presence of lymph nodes can sometimes be determined, but it is exceedingly difficult. Some diagnosticians can classify these cases in children quite frequently, but he himself had not been able to do so.

Dr. Price-Brown, Toronto, asked if this could not be applied to adults as well, and cited a case in which he had been called upon to treat a man who had suffered from difficult respiration for some time. Intubation gave no relief; tracheotomy gave relief for some hours, but then he died. There was no pressure, no diagnosis of any disease, yet the result was fatal.

Dr. Coakley, closing the discussion, said that he had been much interested in what Dr. Jackson had

said about status lymphaticus. He had always questioned why these cases of sudden death should occur where no pathological lesion could be found. In the case he had reported, the first report was status lymphaticus; the second, occlusion by tubercular nodule, the thymus being rather large in size. It was very interesting from the pathological standpoint.

Dr. Cohen had asked about the dyspnea. When the child came to his office, its color was at first perfectly normal, and he saw no indications of any such conditions as the parents described. There was a very slight roughness, and a little dyspnea, but after the child walked up and down across the floor there was considerable dyspnea and moderate cyanosis; it was apparently inspiratory and expiratory, but with the expiratory more marked than the inspiratory. Dr. La Fetra, who has had a wide experience with children, declared that it was an absolutely normal condition to him. There was absolutely no cough, no temperature, nothing to go by.

XVII. ESOPHAGEAL DIVERTICULA, AND REPORT OF A CASE.

EMIL MAYER, M.D., New York.

The difficulties in the way of diagnosis, as well as the question of treatment, were, in the speaker's opinion, sufficient to warrant the presentation of this subject. He emphasized the need of great care in the use of instruments until the nature of the disease was sufficiently known to make their use reasonably safe; disastrous results might follow instrumentation when aneurysm was present. Routine methods should be employed, including ballooning the esophagus, and the esophagoscope should be employed last of all. In the case presented, the x-ray picture was made after a soft rubber tube filled with shot had been inserted. This gave a picture that required no interpreter. His final conclusion was that modern surgery offers much hope for these sufferers.

DR. CHEVALIER JACKSON, Pittsburg, said that he would rather as the first procedure have Dr. Mayer pass the esophagoscope gently and see what he was doing than to have the bougie passed blindly. That seems a much more dangerous procedure than a skillful esophagoscopy.

DR. T. GORDON WILSON, Chicago, reported a unique case of diverticula which occurred in a young lion twenty months of age, showing that diverticula can occur without the age limit. He has observed that as age proceeds one can notice a thickening of the lower walls, but this case showed that the same thing can occur in youth. Another point is that there is a thickening of what Killian called the sphincter muscle of the esophagus.

DR. MAYER, closing the discussion, said that if any of his patients were going to Dr. Jackson or Dr. Mosher, he would wish these gentlemen to examine them any way they liked, but a warning should be sounded for those who have not special skill, and their attention should be called to the possible harm that may be done even by the esophagoscope, which is perfectly safe in trained hands. For this reason, speaking generally, he would advise a routine method of examination.

Book Reviews.

Diseases of the Stomach and Upper Alimentary Tract. By ANTHONY BASSLER, M.D. Philadelphia: F. A. Davis Company. 1910.

This volume constitutes a very valuable work on the anatomy, physiology, chemistry, nosology and therapeusis of the upper alimentary tract. This includes essentially the esophagus and stomach; diseases of the mouth are but briefly considered, and although duodenal ulcer is included, diseases of the pancreas are omitted as belonging more properly with those of the biliary passages. The book is "copiously illustrated with numerous half-tone and line text engravings and fifty-six full-page plates (with nearly one hundred figures, plain and in colors, from original photographs and drawings)." Among the best of these illustrations is a series of fifteen x-ray plates representing various pathologic, gastric and esophageal conditions. The chapters on methods of physical examination seem particularly pertinent and well written. The volume should be useful to internists and general practitioners as well as to specialists in gastro-enterology.

The Diseases of Infants and Children. By EDMUND CAUTLEY, M.D. Cantab., F.R.C.P. Lond., Senior Physician to the Belgrade Hospital for Children; Physician to the Metropolitan Hospital; formerly Casualty Physician and Assistant Demonstrator of Physiology at St. Bartholomew's Hospital. Pp. 1042. New York: Paul B. Hoeber. 1910.

In the preface the author states that this book is written for the general practitioner rather than for students. In consequence, description of some common ailments have been curtailed and more attention given to rare and more recently recognized maladies. Illustrations and charts have been omitted because the author believes that this "kindergarten method of teaching" is a disadvantage to the practitioner "in that the expectation of seeing the typical cases of pictorial illustration increases the danger of overlooking those early stages in which disease is amenable to treatment."

It is, of course, impossible to review in detail a book of over one thousand closely printed pages. The book contains an immense amount of material which is not very well arranged. There are many things in it which are not found in most textbooks, such as a description of the theories of heredity, a chapter on the anomalies of growth, and one on disorders of the higher faculties. The author, evidently, does not appreciate in any way the real meaning and purposes of percentage feeding, and is seemingly unaware of the recent work of German authorities on the disturbances of digestion and metabolism. It seems strange to an American pediatrician to see so much drugging recommended in the treatment of diseases of infancy and childhood. It seems to us that much of the treatment mentioned is irrational and more unnecessary. The book is especially interesting in that it gives the English point of view of pediatrics, which is different from either the American or the German.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, DECEMBER 29, 1910

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal 809 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter payable to

W. M. LEONARD,
101 Tremont Street, Boston, Mass.

CHRISTMAS AND THE PHYSICIAN.

The annual recurrence of the Christmas season affords the physician many objects of interesting contemplation and reflection. Apart from sporadic instances of gastronomic indiscretion, it usually brings a lull in his work, for every one is too busy to pay much attention to the ordinary physical ailments. This is true at hospitals as well as in private practice: every patient, except the sickest, has a cheerful look and the wards assume an unwonted holiday atmosphere. Probably the latter phenomenon is largely produced by the Christmas decorations which modern charity spreads with a lavish hand through so many institutions. There is a therapeutic magic about the holly, even when it is artificial, or, as one might say, synthetic; and its little red berries, like many other boluses, do more good by suggestion than much medicine that is swallowed. Then there is the Christmas tree, which every hospital, great and small, has nowadays, often with an attendant Santa Claus. The children's hospitals are the places to see the Christmas tree in its perfection, for here the tinsel and spangles, the candles and stars, find their most appreciative and unsophisticated enjoyment. The toys of nowadays are likewise wonderful to contemplate, — the ingenious mechanical engines, the fluffy cats and rabbits, and the woodenly expressive "dux" animals. Children easily forget their troubles in joy over such as these. Nor are we much unlike them: after all, life consists of caring for and playing with one toy after another. Perhaps this is the chief secret in the spell of Christmas, that for a time it conciliates all ages on a common meeting-ground of happiness. It is a spell that extends beyond the day and through a whole week, till New Year's comes to symbolize the beginning of life and work anew. Our Christmas, like all else in civilization, like man himself, is a "piebald miscellany," a fantastic mixture of pagan and Christian, of Scandinavian, Teutonic, Celtic and Latin customs, superstitions and observances. It is the truce of the old year, which for a time opens the barriers between earth and Olympus, that the Olympians may descend. The physician must see much of the tragedies of life; let him appreciate also this time of human reconciliation that heals diseases which are beyond his cure with the immemorial anodyne of peace and good-will.

REPORT OF THE SURGEON-GENERAL OF THE NAVY.

The annual report of the Surgeon-General of the United States Navy, dated Aug. 23 last, but just received from Washington, describes "the operations of the Bureau of Medicine and Surgery for the fiscal year ending June 30, 1910, and the health and sanitation of the Navy and Marine Corps for the calendar year 1909." The data of this report present many valuable and interesting statistics, which, with the comment and discussion of Surgeon-General Stokes thereon, make very profitable and instructive reading.

Among the points to which especial attention may be directed is the table showing the relative importance of causes of death. Of 286 deaths in the Navy and Marine Corps in 1909, 51 were due to drowning, 40 to tuberculosis, 19 to pneumonia, and 17 each to typhoid fever and gunshot wounds. That tuberculosis should kill so many men leading a supposedly healthy outdoor life seems surprising until one considers the large part probably played in this disease by predisposition and the fact that conditions aboard a modern warship are far different from those on a sailing vessel; but that more men should die of drowning than from any other cause is unnecessary and preventable. It is proverbial that sailors do not know how to swim. No doubt the percentage of swimmers among sailors is as high as among landsmen, but their opportunities for falling into the water are much greater. To prevent the waste of life consequent upon this deficiency, Dr. Stokes recommends that instruction in swimming be made part of the training of every officer and man, and that his "demonstrated ability to swim a substantial distance, say, 300 yards, and to sustain the head above

water for fifteen minutes in the presence of a light breeze," be made one of the first requirements for his being allowed to remain in the service.

Another point upon which especial emphasis is laid is the maintenance of general physical efficiency in the navy. With the change from sailing to steam vessels, with the specialization instead of general training required of different members of the crew, this has become more and more difficult to secure. Dr. Stokes believes that the present annual physical test does more harm than good, since it puts upon the individual a sudden strain for which he is often unprepared. He therefore recommends the substitution for it of "more recreative and continuous athletic exercise, and for the younger personnel the adoption of the Swedish system of physical training" instead of the present setting-up exercises.

The problem of venereal disease is always one of the gravest among sailors, as indeed it is in civil life. Its importance is indicated by the fact that in 1909 gonorrhea alone constituted over a sixth of all the cases of sickness in our navy, more than any other one disease; and gonorrhea, chancroid and syphilis together comprised over a quarter of all cases. During the same period disability resulting from syphilis was the reason for more discharges from the service than any other one cause. As a means of combating this "greatest damaging disease group," Dr. Stokes urges the enforcement "throughout the entire service, ashore and afloat," of a system of venereal prophylaxis such as has been adopted and practiced with considerable success in the Asiatic and Atlantic fleets. Details of this system are not stated in the present report, but its employment certainly seems to have been of some value.

Finally, in discussing the relatively high incidence of typhoid fever in our navy, the Surgeon-General says: "English, German and American military statistics and experiences point with increasing certainty to the advisability of adopting typhoid vaccination for the protection of persons likely to be exposed to infection," and recommends the extension of compulsory anti-typhoid vaccination "to the entire personnel under the age of fifty years."

These are merely topics selected for comment from among many of equal value and interest which make this report worthy of careful perusal by physicians and sanitarians throughout the country.

STANDARDS IN SELECTION OF RECRUITS FOR THE ARMY.

A RECENTLY published report of the Secretary of War presents significant data relative to causes of rejection of recruits for the United States army. Of 100,996 candidates examined during the past year, only 19% were accepted. The rejections, however, were not all on physical grounds, since a considerable number were for lack of requisite mental, moral or technical qualifications. The standard of physical efficiency required in the army is doubtless very high, and the failure of so many to attain it does not necessarily indicate physical degeneracy among the people. Incidentally, the theoretical selection of the physically fittest to constitute the army of a country illustrates the fallacy of war, since it condemns to celibacy and exposes to disease and death during their years of greatest vigor many of those who should be doing the work and increasing the numbers of the nation. In a large country like ours, with a small army in times of peace, this disadvantage is negligible and is probably more than offset by the gain in discipline of those who serve a limited period. But in countries with a relatively large army and in times of war, as in our Civil War, the fittest are selected to perish, and the less fit physically survive to propagate the species.

SOME GENEROUS PUBLIC BEQUESTS.

THE will of the late Mrs. William O. Moseley, of Newburyport, Mass., which was filed for probate on Dec. 22 in the Essex County Probate Court at Salem, Mass., made public bequests amounting to $370,000. To the Anna Jaques Hospital, Newburyport, is given the sum of $200,000, to be divided into two equal funds, the income only of which is to be used respectively for regular expenses of the hospital and for the maintenance of free beds. A further sum of $10,000 will revert to the hospital after the death of one of the private beneficiaries. Sixty thousand dollars are left to Harvard University "for the establishment of two fellowships to enable medical students of marked ability to pursue their studies abroad." The Moseley Professorship of Surgery was established some years ago in the Harvard Medical School by a gift of $50,000 from Mrs. Moseley's husband. Mrs. Moseley's will further contains bequests of $5,000 each to the Convalescent Home of the Massachusetts General Hospital, the Massachusetts Charitable Eye and Ear Infirmary, and several

general charitable or religious institutions. Mrs. Moseley had also been a liberal donor in charity during her life. Her generous legacies will preserve the memory of these benefactions and increase the debt of gratitude already owed her by the community.

THE RETIREMENT OF DR. JELLY.

The resignation of Dr. George F. Jelly from the various activities with which he has long been identified should not pass unnoticed. Since 1869 he has been closely associated with work in connection with the insane, first as assistant and later as superintendent of the McLean Hospital, and since 1879 as a practitioner in this city, specializing from the first in psychiatry. It is not, however, to his wide recognition as a practitioner in this difficult field that we desire to call attention, but rather to his broader service to the public as examiner for the Registration Department of Boston, a position which he held for thirty years, and as an active member of the State Board of Insanity, of which he was chairman for ten years. In these posts he has always been known as a man of exceptional judgment, combining with a wide and well-considered experience a degree of common sense and wisdom not often seen in dealing with the intricate and far-reaching problems of insanity. These qualities have made him an expert witness sought and trusted in these days of over-refined knowledge on the one hand and of unscrupulous ignorance on the other. In the retirement of such a man from public life, the city, which he has so well served, loses an influence which has always worked for exact justice and fair dealing in a field of endeavor in which firm opinions are alike difficult to form and to maintain. What Dr. Jelly represents is an invaluable asset to any community. His place will be difficult to fill.

MITIGATION OF DROUGHT IN NEW ENGLAND.

In the issue of the Journal for Dec. 15, we commented editorially on the continuance of drought in Massachusetts, and the seriousness of the situation thereby induced in several New England towns. During the succeeding weeks, the shortage of water became even more acute. The supply at West Springfield, Mass., was entirely exhausted, so that drinking water had to be obtained through a temporary line of hose across the toll bridge from Springfield. At Worcester, Mass., the available supply was reduced to one fifth its normal amount and water famine seemed so imminent that all hydraulic elevators and public watering-troughs in the city were cut off. In Connecticut, the cities of New Haven, Norwich, Hartford and Waterbury were all much reduced in water supply. At Greenwich, Conn., the supply fell so short that schools and factories were closed and steam furnaces put out. There was similar shortage in the adjacent villages of Portchester and Rye in Westchester County, New York. Happily, however, the extensive and heavy rain of Dec. 24 has relieved this situation to a considerable extent, and the thaw associated with it has added still more to many reservoirs. The water supply in numerous localities is still scanty, notwithstanding, and, in the absence of further rain, there is likely to be a recurrence of the recent scarcity before the end of the winter.

MEDICAL NOTES.

Birth of Quadruplets. — From Dunellen, N. J., is reported the birth on Dec. 25 to Mrs. John Cortright, of Sebring's Mills, N. J., of quadruplets, three boys and a girl, at her first pregnancy. The children are said to be all living and apparently healthy. Their weights are not stated.

Institute of Dental Pedagogics. — The annual convention of the National Institute of Dental Pedagogics has been held in Washington, D. C., on Dec. 27, 28 and 29 of this week. It was attended by deans of dental colleges throughout the United States and by other official delegates. The subject for discussion by the convention was "The Methods of Teaching Dentistry."

Hookworm in Alabama. — It is reported from Montgomery, Ala., that a recent investigation by Dr. H. G. Perry, a state field agent of the Rockefeller Hookworm Commission, shows that 70% of the schoolchildren of Dothan, Ala., and 75% of the rural population of Houston County in that state, are infected with uncinariasis. These figures corroborate previous estimates of the extent of hookworm infection in the South and of the magnitude of the task of its eradication.

Abatement of the Cholera Epidemics. — During the week ending Dec. 24, only 9 new cases and 3 deaths of Asiatic cholera were reported from Italy, as against 22 cases and 7 deaths during the preceding week.

Report from Lisbon states that the cholera epidemic in Madeira is also decreasing. On Dec.

19 the Portuguese cruiser *Almirante Reis* was dispatched from Lisbon to Funchal with a number of physicians and marines and with fresh supplies of medicine and food.

A CENTENARIAN. — Mrs. Margaret Cassidy, who died on Dec. 24 at the House of the Good Shepherd in Philadelphia, was said to have been born in Scotland in 1805. She was the oldest inmate of the House, in which she had lived for the past thirty years. It is believed that she has no surviving relatives.

TWO OPIUM SEIZURES. — Two large seizures of opium in this country were reported last week. The first was at Buffalo, N. Y., where, in a raid by federal officers, $5,000 worth of the crude drug were seized and ten Chinamen arrested on a charge of preparing it for smoking without paying the internal revenue duty. The second seizure was made at San Francisco by customs inspectors, who found and confiscated 75 tins of opium, valued at $4,000, on board the liner *Asia*.

SEIZURE OF ADULTERATED FOODS. — Last week 350 cases of tomato catsup shipped from Mt. Holly, N. J., were seized by United States officials. The catsup is alleged to contain "filthy, decomposed and putrid animal and vegetable substances." On complaint of the federal pure food inspectors, the United States marshal at San Francisco also seized a shipment of tomato paste from New York, supposed to be similarly adulterated.

BUBONIC PLAGUE IN MANCHURIA AND CHINA. — In last week's issue of the JOURNAL we recorded a temporary abatement of the epidemic of bubonic plague in Manchuria. Recent advices from St. Petersburg, from Pekin and from Victoria, B. C., however, report a recrudescence of the disease in Manchuria, and its extension into Mongolia, an adjacent province of northern China. The situation is complicated by flood and famine. It is stated that in Ankin alone 2,500,000 persons are destitute. Under such circumstances, and with the customary Oriental disregard of sanitation, the spread of the plague may be expected to be very rapid and the loss of life enormous.

AN INSTANCE OF BODY-SNATCHING. — We are accustomed to think of burking and body-snatching as obsolete practices of a bygone day. Report from Montreal, Canada, however, records the recent arrest of a former medical student in Jarvis, Ont., for robbing a grave for anatomic material. The grave was found empty and the body it should have contained was discovered in a local cold storage warehouse in a barrel marked "poultry." There was a time when such zeal in the cause of science would have been almost laudable, but in the present state of the anatomy laws in the Dominion such an occurrence is exceedingly unfortunate, since it will bring only misunderstanding and discredit on the medical profession.

TWO LIVING CENTENARIANS. — Mrs. William T. Temple, of Reading, Mass., is said to have been born in that town on Dec. 20, 1810, and celebrated last week the supposed centennial anniversary of her birth. She has spent her entire life in Reading, and has occupied her present home for the past fifty-seven years. In her youth she was a nurse. She married in 1840, and has had five children, of whom the eldest, a son, and the youngest, a daughter, are still living. Her husband died in 1898. She is very deaf, but is otherwise in excellent health.

James Forbes Foster, who is alleged to be one hundred and seven years of age, has recently been evicted from his home in Kansas City. He was born in Buffalo, N. Y., and has always led a roving life as a mine-owner and adventurer. It seems unfortunate that he cannot pass even his declining years in peace.

VON LEIDEN'S KLINIK. — The report that Dr. Von Leiden's Klinik in Berlin has been closed since his death is apparently incorrect. Our readers may be interested to know that the Klinik at 4a Cornelius Strasse is being continued under the direction of Excellenz Von Leyden's pupil and assistant, Prof. Dr. Paul Lazarus.

DANGERS OF THE MISTLETOE. — It is reported from Blytheville, Ariz., that three small children in the neighboring town of Luxora died on Dec. 25 of acute poisoning from eating mistletoe berries. The berries of English mistletoe are not commonly considered toxic; in fact, among the medieval pharmacologists they used to be employed as an antispasmodic. The external use of the mistletoe is more pleasant, though at times even more dangerous, than its internal administration.

NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL. — The New York Post-Graduate Medical School and Hospital is making arrangements, on the completion of its new buildings, greatly to extend the scope of its laboratory work, both as an adjunct to the increased hospital service, — which will consist of approximately 400

beds, — and as regards departments for teaching pathology, bacteriology and clinical organic chemistry.

In addition to the laboratory for tropical medicine, in collaboration with the medical departments of the army and navy, it is proposed to provide ample space for the separate laboratories for pathology, bacteriology and chemistry under one general direction.

Cats and Tuberculosis. — A physician from Cleveland, Ohio, has recently called renewed attention to the liability of the dissemination of tuberculosis by domestic cats. It has for some time been recognized that cats are particularly prone to tuberculosis, diphtheria and other infections, which they are, therefore, likely to transfer between individuals and from one family to another. The habit of fondling pet animals is always dangerous, particularly on the part of children, whose affections are likely to outstrip their discretion. In other climates, the dog is even more liable to be a disseminator of serious infections, but among us the cat is probably more often a source of disease.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston.— For the week ending at noon, Dec. 27, 1910, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 52, scarlatina 25, typhoid fever 2, measles 37, smallpox 0, tuberculosis 55.

The death-rate of the reported deaths for the week ending Dec. 27, 1910, was 18.36.

Boston Mortality Statistics. —The total number of deaths reported to the Board of Health for the week ending Saturday, noon, Dec. 17, 1910, was 217, against 215 the corresponding week of last year, showing an increase of 2 deaths and making the death-rate for the week 16.79. Of this number 118 were males and 99 were females; 212 were white and 5 colored; 122 were born in the United States, 93 in foreign countries and 2 unknown; 40 were of American parentage, 148 of foreign parentage and 29 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 36 cases and 4 deaths; scarlatina, 33 cases and 1 death; typhoid fever, 2 cases and 2 deaths; measles, 26 cases and 1 death; tuberculosis, 62 cases and 24 deaths; smallpox, 0 cases and 0 deaths. The deaths from pneumonia were 34, whooping cough 2, heart disease 19, bronchitis 3. There were 11 deaths from violent causes. The number of children who died under one year was 29; the number under five years 46. The number of persons who died over sixty years of age was 67. The deaths in public institutions were 85. Cerebrospinal meningitis, 1 case and 1 death.

Of the above infectious diseases the following were non-residents: Consumption, 2 cases. Scarlet fever, 2 cases. Diphtheria, 2 cases and 1 death. Measles, 1 death.

Deducting deaths of non-residents, the total is 202 and the death-rate is then 15.63.

Appointment of Chief Veterinarian. — Dr. P. J. Cronon, of Boston, was last week appointed chief veterinarian of the city street department, to succeed Dr. L. H. Howard, the former incumbent, who recently resigned.

Meeting of Army Nurses. — A meeting of the Massachusetts Army Nurses' Association was held in Dorchester last week. This organization consists of the survivors of those women from Massachusetts who served as army nurses during the Civil War. At the meeting there were several addresses, followed by a reception.

Gift to the Deaconess' Hospital. — The gift is announced, from a resident of Concord, Mass., of one hundred acres of land in that town to the New England Deaconess' Hospital, together with $10,000 towards the erection and maintenance there of a new hospital building, similar to the one now in Longwood. This gift, of charity and sentiment, should prove a source both of benefit to the town of Concord and of happiness and satisfaction to the generous donor.

Suspension of Druggists' Licenses. — The Boston Licensing Board has recently suspended until April 30, 1911, the license of two South Boston druggists to sell intoxicating liquor. This action was taken on complaint by the police board that the druggists in question made illegal sales of liquor on Sunday to members of the force. The suspension of their licenses is not only a just punishment, but also will act in the interest of temperance and of police efficiency.

Illegal Sales of Milk and Vinegar. — In the central municipal court last week two milk dealers, of Cambridge, Mass., and Somerville, Mass., respectively, were fined $10 each for having in possession, with intent to sell, milk not up to the standard required by law. Another dealer was fined $10 for selling milk without a license, and a fourth $10 for selling as pure cider vinegar

vinegar that was not such. Another milk dealer, who admittedly sold loose milk from an open receptacle, in violation of the ordinance of the board of health, was fined $10 and appealed his case to the Supreme Court on the ground that in the district which he supplies the conditions are such as to make it impracticable to supply milk as required in sealed receptacles.

REPEATED REQUEST FOR CITY HOSPITAL APPROPRIATION. — In the issue of the JOURNAL for Dec. 15, we noted the recommendation by the trustees of the Boston City Hospital of an additional loan appropriation of $297,800. The request for this appropriation has been repeated, on the ground that there is urgent need of provision for the accommodation of contagious cases which cannot be received at any other large Boston hospital.

THE HARVARD CANCER HOSPITAL. — Work has been begun and is now well under way in the construction of the new Harvard Cancer Hospital, on the corner of Vandyke Street and Huntington Avenue, near the Harvard Medical School; and it is expected that the building will be completed by Sept. 1, 1911. An additional fund of $250,000 is needed as an endowment for its maintenance, and it is to be hoped that generous contributions may complete this sum by the time the hospital is opened.

APPOINTMENT TO THE STATE BOARD OF INSANITY. — On account of ill health, Dr. George F. Jelly, of Boston, recently resigned his position as a member of the Massachusetts State Board of Insanity. As his successor, Governor Draper nominated, last week, Dr. Edward Wyllys Taylor, of Boston, instructor in neurology at the Harvard Medical School, and one of this JOURNAL's editors. Dr. Jelly's years of faithful and efficient service have set a particularly high standard of duty for the office to which Dr. Taylor is called.

CHANGES AT ST. ELIZABETH'S HOSPITAL. — It is announced that St. Elizabeth's Hospital, Boston, has recently acquired a large and valuable tract of land in Brighton on which to erect a new hospital building. Coincident with this announcement is that of the appointment of Dr. William A. Brooks, Jr., of Boston, as chief of the surgical staff, with Dr. Edward A. Supple, of Boston, as his first assistant; and of Dr. Thomas F. Harrington, of Boston, as chief of the medical staff, with Dr. Michael J. Cronin, of Roxbury, as his first assistant. This reorganization of the hospital staff will presumably become operative before the removal of the hospital to its new site.

RELOCATION OF FOXBORO STATE HOSPITAL. — In a recent special report to the Massachusetts Legislature, the trustees of the Foxboro State Hospital for Inebriates recommended the removal of this institution to more suitable and extensive quarters. It is now announced that 648 acres of land in the townships of Norfolk and Walpole, Mass., have been selected for this new site, and will shortly be purchased, with the buildings thereon, from an appropriation available for the purpose. The transfer of patients will not begin until spring and will be gradual. It is intended that the institution, which will be conducted on the cottage system, shall be a model for the rational, scientific treatment of inebriety. "The hospital for men will receive, under the new conditions, patients who come voluntarily or who are committed upon application; young habitual drunkards placed on probation by the court on condition that they spend a specified time at the hospital, and suitable cases transferred on parole from the colony for the detention of chronic drunkards. The hospital for women will receive voluntary and probation cases. The detention colony will receive non-criminal, habitual drunkards from the criminal courts on indeterminate sentence." The old buildings at Foxboro will be held by the State Board of Insanity for use in the accommodation of the insane in Massachusetts.

NEW YORK.

SATURDAY AND SUNDAY ASSOCIATION. — The Saturday and Sunday Association is making an effort this year to secure $200,000 by its annual collection, or about double the amount usually raised. In answering its appeal, Mayor Gaynor, who is, *ex officio*, chairman of its distributing committee, has sent a check for $50 enclosed in a letter in which he commends the purposes of the association to the public.

HUNTING CASUALTES. — In New York state during the recent open season for deer, there were 28 hunting casualties, 3 men were killed and 3 seriously injured through being mistaken for deer. Through carelessness or accident 16 others were killed and 6 injured, and practically all these casualties were in the Adirondack region. Last year the record was much less serious, there having been 15 casualties, of which one third proved fatal.

Verdict against Physicians for Performing an Autopsy. — A verdict for $8,000 was rendered by a jury in the Queens County Supreme Court, Long Island City, Borough of Queens, on Dec. 12, in a suit for $10,000 damages brought against two physicians for performing an authorized autopsy on the body of a patient who died last year in St. Joseph's Hospital, Far Rockaway. The action was undefended, one of the physicians being absent in Cuba and the other denying that he was one of the defendants, and the case will no doubt be appealed. It was stated by the counsel for the plaintiffs, who were the children of the deceased, that this was the first case of the kind ever brought to trial in the state of New York.

Annual Report of Charity Organization Society. — In the twenty-eighth annual report of the Charity Organization Society, just issued, considerable attention is devoted to the subjects of over-work and occupational diseases. In the discussion of the latter it is stated that the existence of a serious form of phosphorus poisoning in match factories in this country has recently been revealed, contrary to popular impression. A bill placing a prohibitive tax on the use of the poisonous but less expensive variety of phosphorus in the manufacture of matches, the report goes on to say, has been introduced into Congress. By this legislation, when secured, the United States will finally take its place on this point with all the other important commercial countries of the world.

An Alliance between the Presbyterian Hospital and Columbia Medical School. — It has just been announced that when the new Presbyterian Hospital, which is to be erected on a site adjoining the Rockefeller Institute, has been finished, an alliance will go into effect between the hospital and the medical department of Columbia University which will correspond with the conditions existing at the Johns Hopkins University and Hospital. While for many years most of the visiting staff of the Roosevelt Hospital have been professors or instructors in the Columbia Medical School, it would appear that there has never been any official connection between the two institutions. Under this new arrangement, however, the appointments to the medical and surgical staff of the Presbyterian Hospital will be under the direct control of the medical school. Through the liberality of the late John S. Kennedy and others the hospital authorities have ample funds for the construction of the new buildings, and now it is stated that the sum of $1,300,000, contributed by Edward S. Harkness and another donor whose name is withheld, is available for carrying out the proposed alliance with Columbia. Among the features agreed upon is a department for research work, which is to be under the control of the university. It is also announced that in addition to his other gift, Mr. Harkness will provide $300,000 for the erection and equipment of a special surgical pavilion at the hospital. The contemplated new buildings of the College of Physicians and Surgeons will no doubt be located in the immediate vicinity of the new hospital.

Increase and Prevention of Insanity. — A campaign for the prevention of insanity in the state of New York, which is to be carried on under the direction of the State Charities Aid Association, was inaugurated on Dec. 23 at the Academy of Medicine, at a meeting held under the auspicies of the Section on Public Health of the Academy. Dr. A. W. Ferris, President of the State Commission in Lunacy, said that the state was now caring for 35,520 mental defectives, of whom 32,658 were insane, a proportion of 1 lunatic to every 289 of the population. Last year 6,400 new cases were admitted to the state hospitals, a net increase of 1,200. The increase of known cases, however, was no doubt due largely to the more accurate methods of diagnosis now practiced, and the more thorough attention paid to the insane. He assigned alcohol as the most prominent cause of insanity, nearly 30% of all the cases under the charge of the state being due to this. Another important cause was too free immigration. The total foreign population was 35%, but the percentage of foreign-born lunatics in the institutions was 45%. Among the measures mentioned by Dr. Ferris which might be adopted are the following: Field work in hospital districts by special physicians attached to the staff; co-operation of physicians and special societies; social service by lay committees; a general campaign of interest and education; special care of the backward or abnormal child. Prof. M. Allen Starr said that he looked upon the campaign most hopefully. Only 30% of cases that reached the insane asylums were of classes not susceptible of preventive treatment; 20% produced by alcohol and drugs are not beyond hope of control, and 50% due to infections, auto-intoxication, emotional strain and overwork are preventable. An address was also made by Homer Folks, Secretary of the

State Charities Aid Association, in which he told how it was purposed to conduct the campaign and stated that already voluntary contributions sufficient to carry on the work for three years had been received.

4. Pratt summarizes his historical and experimental article on diabetes as follows: Despite opposing theories and conflicting observations in regard to the relation of the pancreas to diabetes, some facts have been definitely ascertained. The total removal of the pancreas always leads to a fatal diabetes. Atrophy of the pancreas produced by excluding all the pancreatic juice from the intestine is associated with a marked decrease in the limit of assimilation for sugar. Transplantation of a portion of the pancreas prevents the development of diabetes when the rest of the gland is extirpated. Lesions of the islands of Langerhans are found in most cases of diabetes. They are usually associated with changes in the acini. In the progressive atrophy which follows the occlusion of all pancreatic ducts in dogs and cats, both islands and acini are gradually destroyed. All the islands may disappear, however, without diabetes resulting. The conclusion is justified that the pancreas has an internal function concerned with the metabolism of sugar. The nature of this function, relation of the islands to the acini, the significance of histologic changes in both structures, still await solution.

7. Sever points out that tuberculosis of the ankle-joint and bones of the foot in children is insidious in onset, chronic in its course and attacks usually young children. The expectant or conservative method of treatment is preferable to the operative. Time is saved and deformity less under the conservative than by the operative method. There is also less danger of secondary joint involvement and general tuberculosis by pursuing the non-operative plan. The prognosis is fairly good for hips, but poor for a good ankle-joint in which there is no disability. The results are good for joint motion when the disease affects the metatarsal bones. [E. H. R.]

6. HIRSCH, C. T. W. *Motoring Notes.*

1. Bastian first emphasizes the wide discrepancy of the present views as to the pathogenesis of acute myelitis. He then discusses the etiology and pathogenesis of this

condition according to his own views and briefly mentions acute poliomyelitis as an allied condition. He believes that the evidence is overwhelming that in the great majority of cases of acute myelitis and poliomyelitis the affection is caused not by an inflammation, but by thrombosis of some of the vessels of the spinal cord where in the latter disease it is not due to a special degenerative process.

4. Cobbett discusses the question of immunity in tuberculosis and the healing of any tuberculous process by the gradual acquiring of this immunity. He believes that the severity of the disease in any given case is in direct proportion to the number of bacilli present in the body. He believes that immunity can best be acquired by rest, and urges rest as the main feature of the treatment of this disease in its early stages. [This article is written by a pathologist; the sentiments herein expressed hardly accord with those of the majority of clinicians at the present time. — J. B. H.] [J. B. H.]

15. Von Eicken, C., *et al. Discussion on Direct Methods of Examining Air and Food Passages.*
16. Hett, G. S., *et al. Discussion on the Removal of the Tonsils.*

1. Morison discusses syphilis, cancer and tuberculosis as they simulate each other and as they occur in various combinations. Syphilis and tuberculosis he considers a deadly combination; cancer and syphilis are firm allies; if a person over sixty years of age contracts syphilis, his death from cancer may be anticipated.

5. Grünbaum, Hewlett, Bryce, Harley and others discuss the value of lactic acid as a therapeutic measure as used in sour milk preparations. The general opinion seemed to be that although in certain cases of constipation, rheumatic states, etc., it was of value, as a general thing the same good result could be gained by older and simpler methods. Moderation in eating is much more important than the drinking of sour milk.

7. Meyer believes that it has been clearly demonstrated that lime salts diminish the permeability of the walls of the blood vessels.

11. Wenckebach gives an excellent general consideration of the therapeutic and physiologic effects of digitalis; Mackenzie considers the subject from the clinical standpoint; Turnbull believes in pushing the drug up to full doses in order to get good results. The danger of doing harm is so slight as to be neglected. Raised blood pressure he believes to be no contra-indication.

13. Mathison makes an urgent plea for the use of creosote and potassium iodide in pneumonia. He speaks of a series of 20 cases with no mortality and with abortions in 4 cases. His arguments are not convincing. [J. B. H.]

17. Spicer, R. H. S. *Cancer of the Throat.*

2. Rudolf, in a very practical article, discusses high blood pressure in arteriosclerosis and its treatment. The cause of a high blood pressure in this condition is usually to be classed among one or more of the following groups:

(1) Toxemia of some kind which directly poisons the vessel walls, such as syphilis.

(2) Some toxin which directly raises the blood pressure, as in the case of adrenal tumors.

(3) Compensatory high blood pressure.

(4) Simple nervousness.

(5) Arterial disease alone.

The treatment of this condition he discusses along with the cause. He compares the pressure-lowering effects of nitroglycerine, sodium nitrate, erythrol tetranitrate and mannitol nitrate. The latter maintains its effect even longer than erythrol and is to be preferred. He does not discuss baths, massage and other methods of reducing blood pressure.

9. Barr carried out an interesting experiment on the cadaver in which a lumbar puncture was done and the needle left in. After this a one-half-inch trephine opening was made above and slightly behind the left ear and a canula thrust into the left lateral ventricle. Carmine-colored fluid was then allowed to flow through the needle, which in less than a minute appeared through this canula in the lumbar region. The writer was about to continue this research on animals when a boy came into the hospital with diffuse septic meningitis. All other methods failing, and the boy being in a moribund condition, this operation was performed and large amounts of pus washed out through the lower opening. The pulse dropped and the general condition of the patient greatly improved. He died later on. The diagnosis was confirmed by autopsy.

14. Pegler, in a careful paper, discusses and classifies the various kinds of headaches associated with obstruction in the nasal passages. He presents in tabular form the characteristics of headaches due to other causes and their differential diagnosis from headaches of nasal origin.

2. Sahli in the year 1907 described a new apparatus for detecting the energy or working power of the pulse. He has worked over this method and now presents it in full with diagrams of the apparatus and a description for figuring out the energy of the pulse wave. He considers that these determinations will be of considerable value in regard to diagnosis and prognosis.

3. As a result of simultaneous registering of heart sounds and the electrocardiogram the following facts have been established: The first heart sound begins about .05 to .07 seconds after the beginning of the point of the initial rise; the second heart sound about .02 second after the following wave. The systolic murmur of mitral regurgitation begins at the time that the first sound begins in the normal heart, while the systolic murmur of aortic insufficiency begins later by about .06 to .09 second. The diastolic murmur of aortic insufficiency comes at the time of the second heart sound. In mitral stenosis, as a rule, the first sound comes late; the height of the stenosis murmur also comes after the first sound should begin. With reduplication of the first sound the first part is not caused by the auricles contracting. [C. F., JR.]

16. TAVEL, E. *The Advantage of Carrard's Patient Lifter.*

1. Krehl says that he has frequently seen symptoms of thyroidism follow the use of iodides, and that these symptoms may be progressive and persistent. He believes that this is more likely to happen in cases having demonstrable disease of the thyroid gland or nervous symptoms suggestive of hyperthyroidism. He, therefore, advises against the use of iodine in all such cases. Cardiac "neuroses," loss of weight, irritability or any one of these complex functional disorders, a variety of minor complaints and even Graves' disease itself may be traced to iodine. The writer has not found that any one preparation is less dangerous than another; neither is he prepared to say in what cases iodine can be used without risk.

2. The evidence presented by the writer in the form of statistics points clearly to excessive smoking as a cause of the arteritis of intermittent claudication. He points out also that when no pulse can be felt in an artery there may be a systolic murmur produced by the passage of blood through it. Another interesting observation is that of 14 cases of claudication who smoked enormously, 12 had general arteriosclerosis. Erb has recently looked for apocamnosis as described by Goldflam and has found it in every case, 6 in all. After a little exercise of the legs and feet, blanching of the skin of these parts occurs.

4. Basing his deductions upon experimental work and observations, Strasburger gives an interesting discussion of the functions of the heart and blood vessels in maintaining the circulation. His arguments are too complex to be summarized briefly.

7. In this article Haudek publishes the results of observations on a much larger number of cases than he had had for the previous paper. He reaffirms and adds to the points which he brought out then, and says that he now believes penetrating ulcers of the stomach to be common rather than exceptional. His success in recognizing such with the fluoroscope is astonishing. The diagnosis was proven by autopsy or operation in most of his cases. [G. C. S.]

8. The author, in discussing the treatment of severe wounds where dirt and infection are ground into the edges of the wound and the tissues torn and bruised, declares that the best treatment is to disinfect by means of the scissors and forceps. Cutting away all torn margins and shreds of tissue he considers of more importance than irrigations or chemical antiseptics. When all the surfaces

of the wound are freshened and cleaned in this way he believes in approximation of the wound loosely so as to allow drainage, but tightly enough to insure first intention healing. [J. L. H.]

2. In his article on surgery of the esophagus, Wendel writes mostly on the treatment of cancer, but has short sections on the cure of cardiospasm and of diverticula. Wendel himself has attempted radical operation in three cases of cancer, two of which died immediately afterwards. The operation he describes consists of opening the mediastinum, cutting the esophagus just below the tumor, and then, through an incision in the left neck, dissecting free the lower end of the proximal section and removing the cancerous segment. Following this, one of three things is done: The two ends are united if possible, both cut ends are sutured to the skin and connected by a canal of skin or by a rubber tube, or the lower piece is inverted and closed, and a gastrostomy done. The argument for undertaking such an operation lies mainly in the tendency of cancer in this situation to spread only by community, and not by metastasis. If the tumor is low in the esophagus, laparotomy may be combined with thoracotomy. The chief difficulty in the technic lies in the securing of exact closure of the pleura, provided this is torn, and of course some differential pressure apparatus must be used.

As regards cardiospasm, Wendel, in a case undilatable by sounds, performed a cardioplasty as one would a pyloroplasty, with excellent result. He has also done one extirpation of a diverticulum, with good success.

[G. G. S.]

Miscellany.

HARVARD PUBLIC MEDICAL LECTURES FOR 1911.

ANNOUNCEMENT is made of the annual series of free public medical lectures to be given during the first four months of the coming year at the Harvard Medical School by members of the faculty and other instructors. This year the Saturday evening lectures have been omitted, and the present series will be held only on Sunday afternoons at four o'clock. The popularity of these lectures seems now well established, and their possibilities of value in the desirable education of the people in medical subjects are obvious. The announcement of topics for the current season is as follows:

Jan. 1, Dr. R. W. Lovett, "Infantile Paralysis." Jan. 8, Dr. Abner Post, "Syphilis." Jan. 15, Dr. Otto Folin, "The Use and Abuse of Preservatives and Other Chemicals in Food Products." Jan. 22, Dr. S. A. Hopkins, "The Mouth in Its Relation to Disease." Jan. 29, Dr. E. H. Bradford, "Spinal Curvature; What can be Done to Keep Our School Children Straight." Feb. 5, Dr. Charles H. Williams, "The Correction of Blindness, Especially in Young Children." Feb. 12, Dr. Charles S. Minot, "Age." Feb. 19, Dr. Theobald Smith, "The Duties of the Individual in the Maintenance and Improvement of the Public Health." Feb. 26, Dr. E. E. Southard, "Heredity in Mental Disease." March 5, Dr. W. B. Cannon, "Vision and Some of Its Illusions." March 12, Dr. M. H. Richardson, "On Surgical Diseases and Their Mechanical Nature; What the Layman should understand of Their Early Symptoms and Importance." March 19, Dr. L. J. Henderson, "What is Food?" March 26, Dr. Charles V. Chapin, "How the Individual can protect Himself against Infection." April 2, Dr. J. G. Mumford, "The Safety of Surgical Operations." April 9. Dr. C. M. Green, "The Personal Hygiene of Women." (To women only.) April 16, Dr. Franklin W. White, "Indigestion; Its Causes and Treatment." April 23, Dr. Walter J. Dodd, "The Roentgen Ray in Medicine and Surgery." April 30, Dr. Harvey P. Towle, "Some Common Diseases of the Skin."

Correspondence.

ANTITYPHOID SANITATION *vs.* INOCULATION.

BROOKLINE, MASS., Dec. 19, 1910.

Mr. Editor: In your editorial in the JOURNAL of Dec. 8, on "Typhoid Fever Epidemics," you made the following statement: "The continued recurrence of such epidemics serves only to re-emphasize the insidious dangers of typhoid fever and *the seeming impossibility of its extermination by even the wisest sanitary provisions.*" As wise sanitary provisions have been sufficient in certain sections of Germany to prevent such epidemics and practically stamp out the disease, I think the above statement should be amended to read "such epidemics serve to re-emphasize the inefficiency or lack of sanitation in many parts of the United States."

Of the four epidemics to which you refer, three are said to be due to defective water or sewerage systems. As many communities in this country have demonstrated that water and sewerage systems can be provided from which there is practically no danger of typhoid infection, certainly these three epidemics cannot be said to emphasize the impossibility of exterminating typhoid by wise sanitation.

In regard to the fourth epidemic, which was due to infected milk, information is not at hand to show that the infection of the milk was due to the neglect of sanitary measures. The chances are, however, that either the case from which the milk was infected, or some other case in the chain of infection preceding that case, was the result of sanitary negligence. As far as I know, there is no rural district in this country where efficient sanitary precautions are taken to prevent the spread of infection from typhoid patients. Even when a case of typhoid is reported to the local health board, no use is made of the information. Usually, the case is not even visited for the purpose of giving instructions. It is no wonder that typhoid continues to flourish in the country districts and is constantly

12483
Ro

carried thence to the cities, sometimes in sharp epidemics, as in the one at Annapolis, to which you refer.

While I realize, Mr. Editor, that the purpose of your editorial was to call attention to the widening field for antityphoid inoculation, the great value of which has been so clearly demonstrated, I think it should be made very clear that its more general use — that is, outside of hospitals and the army — is advisable, not because sanitary science is unable to control typhoid, but because of our failure to follow the advice of sanitarians. It is much more rational for us to work for improved sanitation as a means of preventing typhoid than for the more general use of inoculation.

Good progress is being made in Massachusetts in improving water and sewerage systems under the able leadership of our State Board of Health, but practically nothing is being done, especially in the country districts, to secure efficient disinfection of the excreta of all known cases and to prevent contact infection. The infection from a case of typhoid fever may extend so far beyond the limits of the town in which it occurs that the precautions which are taken should not be a matter for "Local Option." If we must wait for each local board of health to undertake of itself efficient measures to prevent typhoid infection, it will be years, yes, centuries, before we shall have such control over the disease as has Germany with its centralized sanitary authority. The precautions to be taken by the local boards of health in typhoid should be prescribed by the public statutes of the state, just as vaccination, medical inspection of schools and many duties of local boards of health are at present prescribed, and the enforcement of these measures should be supervised by the State Board of Health. When each case of typhoid is surrounded by the same precautions that we would use for a case of cholera, there would be no need to consider the general adoption of antityphoid inoculation.

Very truly yours,

FRANCIS P. DENNY, M.D.

THE IMPORTANCE OF HUMIDITY IN THE TREATMENT OF COUGH.

CAMBRIDGE, Dec. 23, 1910.

Mr. Editor: The textbooks do not lay particular stress on moisture in the air of the room in treating patients with certain respiratory diseases in which cough is a prominent as well as troublesome feature. Two cases have been brought to my attention where cough was a distressing feature which did not respond to medicinal treatment. The first case was in a child of four years who had a persistent irritant cough after an attack of whooping cough. No result was obtained with medicinal treatment. The father of the child, having expert knowledge of the importance of temperature and humidity, strung several sheets soaked in water in the room at night. This was done several nights in succession and immediate relief followed and later a cure. The second case was in an elderly woman who had "taken cold." After a few days she recovered, although she had a bothersome cough at night. This continued some time notwithstanding treatment by her physician. The physician was advised to try the above treatment, with prompt success.

I now wish to add a third case; a patient thirty years old, living in a steam-heated apratment, with a temperature of an average of 70°, with no system of humidifying the air. I treated the patient for ten days for acute laryngitis with cough a constant accompaniment, and especially troublesome at night. There seemed to be little or no result with various drugs. The temperature, on the two days when the following simple treatment was commenced, hovered around zero. I instructed the patient, who had to this time slept with windows wide open, to close them to an inch, allowing just a moderate amount of air to enter the room. The room's temperature did not exceed 72°. A basin of water and a moistened cloth were then placed in the room. No other treatment was given. This was repeated three nights and days with complete cessation of the cough.

Very truly yours,

JAMES A. HONEY, M.D.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, DEC. 17, 1910.

PHYSICAL DIRECTOR (MALE).

THE United States Civil Service Commission announces an examination on Jan. 21, 1911, to secure eligibles from which to make certification to fill a vacancy in the position of physical director and assistant disciplinarian at $800 a year at the Haskell Institute, Kansas, and vacancies requiring similar qualifications as they may occur in the Indian Service, unless it shall be decided in the interest of the service to fill the vacancy by reinstatement, transfer or promotion. It will not be necessary for competitors to report at any place for examination. Their eligibility for the position will be determined upon the evidence furnished in application and examination Form No. 1312 concerning their education, training and experience. Applications for this position will be accepted only from men who are graduates of medicine.

RECENT DEATH.

DR. CLARA A. SWAIN, who died on Dec. 26, at Castile, N. Y., was born in Elmira, N. Y., in 1834. In 1870 she went to India as a medical missionary and is said to have been the first woman physician to go to the Orient in that capacity.
